CLINICAL KEY™

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

**Unlike a conventional search engine, ClinicalKey
is specifically designed to serve doctors by providing
three core components:**

**1 Comprehensive
Content**

The most current, evidence-based answers available for every medical and surgical specialty.

**2 Trusted
Answers**

Content supplied by Elsevier, the world's leading provider of health and science information.

**3 Unrivalled Speed
to Answer**

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit **ClinicalKey.com** for more information and subscription options.

Essentials of Physical Medicine and Rehabilitation

Musculoskeletal Disorders, Pain, and Rehabilitation

THIRD EDITION

Walter R. Frontera, MD, PhD

Professor and Chair (inaugural)
Department of Physical Medicine and Rehabilitation
Vanderbilt University School of Medicine
Medical Director of Rehabilitation Services
Vanderbilt University Medical Center
Nashville, Tennessee
Adjunct Professor
Department of Physiology
University of Puerto Rico School of Medicine
San Juan, Puerto Rico

Julie K. Silver, MD

Associate Professor
Department of Physical Medicine and Rehabilitation
Harvard Medical School
Boston, Massachusetts

Thomas D. Rizzo, Jr., MD

Consultant, Department of Physical Medicine
and Rehabilitation
Mayo Clinic
Jacksonville, Florida
Assistant Professor, Physical Medicine and
Rehabilitation
Mayo Clinic College of Medicine
Rochester, Minnesota

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*We dedicate this book to our mentors, teachers,
colleagues, and students, who have encouraged us
to pursue academic careers with their enthusiasm for
knowledge and learning; to our patients, who often are
our greatest teachers; and to our families, who support
us and provide the foundation for our pursuits.*

Thomas D. Rizzo, Jr., MD

Contributors

ANTOINNE C. ABLE, MD, MSCI

Associate Professor/Clinical, Physical Medicine and Rehabilitation, Orthopedics and Rehabilitation, Vanderbilt University Medical Center, Nashville, Tennessee
Stroke in Young Adults

SOL M. ABREU SOSA, MD, FAAPMR

Clinica de Medicina Fisica y Electrodiagnostico (CMFE), Aguada, Puerto Rico
Ulnar Collateral Ligament Sprain
Stress Fractures of the Lower Limb

FARSHAD ADIB, MD

Division of Sports Medicine, Boston Children's Hospital, Harvard Medical School, Boston, Massachusetts
Posterior Cruciate Ligament Sprain
Quadriceps Tendinopathy and Tendinitis

MEENA AGARWAL, MD, PhD, MS, Dip Urol, FRCS, FRCS(Urol)

Consultant Urological Surgeon and Senior Lecturer, University Hospital of Wales and Cardiff University, Heath Park, Cardiff, United Kingdom
Neurogenic Bladder
Neurogenic Bowel

MARYAM R. AGHALAR, DO

Cancer Rehabilitation Fellow, Rehabilitation Medicine Service, Memorial Sloan Kettering Cancer Center, New York, New York
Chemotherapy-Induced Peripheral Neuropathy

venu AKUTHOTA, MD

Professor and Vice Chair, Physical Medicine and Rehabilitation, University of Colorado School of Medicine, Aurora, Colorado
Collateral Ligament Sprain
Iliotibial Band Syndrome
Meniscal Injuries

JOHN D. ALFONSO, MD

Assistant Professor, Department of Rehabilitation Medicine, University of Texas Health Science Center, University Hospital Wound Care Center, San Antonio, Texas
Plexopathy—Brachial
Plexopathy—Lumbosacral

JOSEPH T. ALLEVA, MD, MBA

Division Head, Division of Physical Medicine and Rehabilitation, Department of Medicine, NorthShore University HealthSystem; Clinical Assistant Professor,

University of Chicago, Pritzker School of Medicine, Chicago, Illinois

Cervical Sprain or Strain
Piriformis Syndrome
Patellar Tendinopathy (Jumper's Knee)
Patellofemoral Syndrome

ERIC L. ALTSCHULER, MD, PhD

Associate Professor, Department of Physical Medicine and Rehabilitation, Rutgers New Jersey Medical School, Newark, New Jersey
Complex Regional Pain Syndrome
Central Post-Stroke Pain (Thalamic Pain Syndrome)

JOAO E.D. AMADERA, MD, PhD

School of Medicine, University of São Paulo; Director of the Spine Center, Hospital do Coração, São Paulo, Brazil
Low Back Strain or Sprain
Baker Cyst

EDUARDO AMY, MD

Assistant Professor, Physical Medicine, Rehabilitation, and Sports Medicine Department, University of Puerto Rico School of Medicine, San Juan, Puerto Rico
Anterior Cruciate Ligament Tear

ANNA BABUSHKINA, MD

Assistant in Orthopaedic Surgery, Hand Surgery, Massachusetts General Hospital, Boston, Massachusetts
Wrist Osteoarthritis

JOHN R. BACH, MD

Professor and Vice-Chairman, Department of Physical Medicine and Rehabilitation; Professor of Neurosciences, Rutgers New Jersey Medical School, Newark, New Jersey
Pulmonary Rehabilitation for Patients with Lung Disease
Pulmonary Rehabilitation (Neuromuscular)

ALLISON BAILEY, MD

Director and Founder, Integrated Health and Fitness Associates; Instructor, Harvard Medical School, Mount Auburn Hospital, Cambridge, Massachusetts
Pelvic Pain

MOON SUK BANG, MD, PhD

Department of Rehabilitation Medicine, Seoul National University College of Medicine, Seoul, South Korea
Cervical Dystonia
Phantom Limb Pain

ALPESHKUMAR BAVISHI, MD

Pulmonary Fellow, Rutgers New Jersey Medical School,
Newark, New Jersey

**Pulmonary Rehabilitation for Patients with Lung
Disease**

WILLIAM J. BECKWORTH, MD

Assistant Professor, Physical Medicine and Rehabilitation
and Orthopaedic Surgery, Emory University, Atlanta,
Georgia

Intercostal Neuralgia

KEITH A. BENGTSON, MD

Director of Hand Rehabilitation, Physical Medicine and
Rehabilitation, Mayo Clinic, Rochester, Minnesota

Trigger Finger

ANDREW R. BERMAN, MD

Associate Professor of Clinical Medicine, Rutgers
New Jersey Medical School, Newark, New Jersey

**Pulmonary Rehabilitation for Patients with Lung
Disease**

OMAR M. BHATTI, MD

Clinical Assistant Professor, Department of Rehabilitation
Medicine, University of Washington, Seattle, Washington

Hamstring Strain

PETER BIENKOWSKI, MD

Orthopaedic Surgeon, Carlton Sports Medicine Clinic,
Carlton University, Ottawa, Ontario, Canada

**Posterior Cruciate Ligament Sprain
Quadriceps Tendinopathy and Tendinitis**

WILLIAM L. BOCKENEK, MD

Chief Medical Officer, Carolinas Rehabilitation; Chair,
Department of Physical Medicine and Rehabilitation,
Carolinas Medical Center, Charlotte, North Carolina

Heterotopic Ossification

KATH BOGIE, DPhil

Adjunct Assistant Professor, Department of Orthopaedics
and Biomedical Engineering, School of Medicine, Case
Western Reserve University; Senior Research Scientist,
Advanced Platform Technology Center, Louis Stokes
Cleveland Department of Veterans Affairs Medical
Center, Cleveland, Ohio

Pressure Ulcers

KRISTIAN BORG, MD, PhD

Department of Rehabilitation Medicine, Karolinska
Institutet, Danderyd University Hospital, Stockholm,
Sweden

Myopathies

JOANNE BORG-STEIN, MD

Associate Professor of Physical Medicine and
Rehabilitation, Harvard Medical School; Director,
Harvard/Spaulding Sports Medicine Fellowship, Boston,
Massachusetts; Medical Director, Spine Center and
Chief of Physical Medicine and Rehabilitation, Newton-
Wellesley Hospital, Newton, Massachusetts

Cervicogenic Vertigo

Fibromyalgia

GLENDALIZ BOSQUES, MD

Clinical Assistant Professor, Physical Medicine and
Rehabilitation, University of Texas Health Science
Center; Chief of Pediatric Rehabilitation Medicine,
TIRR Memorial Hermann, Houston, Texas

Neural Tube Defects

JAY E. BOWEN, DO

New Jersey Sports Medicine, LLC, Cedar Knolls,
New Jersey; Assistant Professor, Physical Medicine and
Rehabilitation, Rutgers New Jersey Medical School,
Newark, New Jersey

Rotator Cuff Tendinopathy

Rotator Cuff Tear

JEFFREY S. BRAULT, DO

Physical Medicine and Rehabilitation, Mayo Clinic,
Rochester, Minnesota

Extensor Tendon Injuries

Flexor Tendon Injuries

COLONEL STEVEN E. BRAVERMAN, MD

Commander, Walter Reed Army Institute of Research,
Silver Spring, Maryland

Ankylosing Spondylitis

DIANE W. BRAZA, MD

Chair, Physical Medicine and Rehabilitation,
Medical College of Wisconsin, Milwaukee, Wisconsin

Upper Limb Amputations

Diabetic Foot and Peripheral Arterial Disease

DAVID T. BURKE, MD, MA

Professor and Chairman, Department of Rehabilitation
Medicine, Emory University School of Medicine,
Atlanta, Georgia

Median Neuropathy (Carpal Tunnel Syndrome)

Traumatic Brain Injury

MABEL CABAN, MD, MS

Physical Medicine and Rehabilitation, University of Texas
Southwestern, Dallas, Texas

Lymphedema

ALISON L. CABRERA, MD

Tennessee Orthopaedic Alliance, Clarksville,
Tennessee

Total Hip Replacement

Knee Chondral Injuries

JUAN A. CABRERA, MD

Assistant Professor, Department of Physical Medicine and
Rehabilitation, Vanderbilt University Medical Center,
Nashville, Tennessee

Total Hip Replacement

MARK CAMPBELL, MD, MSc

Assistant Professor, Department of Medicine, Division
of Physical Medicine and Rehabilitation, University of
Ottawa, Ottawa, Ontario, Canada

Joint Contractures

GREGORY T. CARTER, MD, MS

Medical Director, St. Luke's Rehabilitation Institute,
Spokane, Washington; Clinical Professor, Physical
Medicine and Rehabilitation, University of California
Davis School of Medicine, Sacramento, California;
Clinical Faculty, MEDEX, University of Washington
School of Medicine, Seattle, Washington
Motor Neuron Disease

CHARLES CASSIDY, MD

Henry H. Banks Associate Professor and Chairman,
Orthopaedics, Tufts Medical Center, Boston, Massachusetts
Elbow Arthritis
Olecranon Bursitis
Hand and Wrist Ganglia
Kienböck Disease

DAVID A. CASSIUS, MD

Physiatrist, Seattle, Washington
Costosternal Syndrome

ANDREA CHEVILLE, MD, MSCE

Associate Professor, Physical Medicine and Rehabilitation,
Mayo Clinic, Rochester, Minnesota
Cancer-Related Fatigue

KELVIN CHEW, MBBCh, MSpMed

Senior Consultant, Sports Medicine Department, Changi
General Hospital, Singapore
Greater Trochanteric Pain Syndrome

MARTIN K. CHILDERS, DO, PhD

Professor, Department of Rehabilitation Medicine,
University of Washington, Seattle, Washington
Myofascial Pain Syndrome

SALLAYA CHINRATANALAB, MD

Assistant Professor of Medicine, Division of Rheumatology,
Department of Internal Medicine, Vanderbilt University
Medical Center, Nashville, Tennessee
Systemic Lupus Erythematosus

CHIEN CHOW, MD

Anesthesia Service Medical Group, San Diego, California
Elbow Arthritis

VICTOR CHUNG, MD

Clinical Associate, Otolaryngology, Head and Neck
Surgery, Tufts Medical Center, Boston, Massachusetts
Hand and Wrist Ganglia

DANIEL M. CLINCHOT, MD

Vice Dean for Education, College of Medicine; Associate
Professor, Physical Medicine and Rehabilitation,
The Ohio State University, Columbus, Ohio
Femoral Neuropathy
Lateral Femoral Cutaneous Neuropathy

RICARDO COLBERG, MD

Primary Care Sports Medicine, American Sports Medicine
Institute, Birmingham, Alabama
Hip Adductor Strain

MELISSA COLBERT, MD

Resident Physician, Physical Medicine and Rehabilitation,
Harvard Medical School/Spaulding Rehabilitation
Hospital, Boston, Massachusetts
Cervicogenic Vertigo
Fibromyalgia

EARL J. CRAIG, MD

Clinical Assistant Professor, Department of Physical
Medicine and Rehabilitation; Clinical Assistant
Professor, Department of Medicine, Indiana University
School of Medicine, Indianapolis, Indiana
Femoral Neuropathy
Lateral Femoral Cutaneous Neuropathy

DI CUI, MD

Department of Rehabilitation Medicine, Emory University
School of Medicine, Atlanta, Georgia
Traumatic Brain Injury

CHRISTINE CURTIS, MD

Manhattan Beach, California
Posterior Cruciate Ligament Sprain
Quadriceps Tendinopathy and Tendinitis

CHRISTIAN M. CUSTODIO, MD

Assistant Attending, Rehabilitation Medicine Service,
Memorial Sloan Kettering Cancer Center; Assistant
Professor, Department of Rehabilitation
Medicine, Weill Cornell Medical College, New York,
New York
Chemotherapy-Induced Peripheral Neuropathy

ALAN M. DAVIS, MD, PhD

Associate Professor, Physical Medicine and Rehabilitation,
University of Utah School of Medicine, Salt Lake City,
Utah
Cardiac Rehabilitation

GEORGE W. DEIMEL IV, MD

Department of Physical Medicine and Rehabilitation,
Mayo Clinic, Rochester, Minnesota
Ankylosing Spondylitis

DAVID R. DEL TORO, MD

Professor, Physical Medicine and Rehabilitation, Medical
College of Wisconsin, Milwaukee, Wisconsin
Tibial Neuropathy (Tarsal Tunnel Syndrome)

MATTHEW M. DIESELHORST, MD

Southwest Orthopaedic Specialists, Oklahoma City,
Oklahoma
Hip Labral Tears

TIMOTHY R. DILLINGHAM, MD, MS

Professor and Chairman, Physical Medicine and Rehabilitation,
The University of Pennsylvania, Philadelphia,
Pennsylvania
Upper Limb Amputations
Diabetic Foot and Peripheral Arterial Disease

SUSAN J. DREYER, MD

Associate Professor, Physical Medicine and Rehabilitation,
Orthopaedic Surgery, Emory University, Atlanta,
Georgia
Intercostal Neuralgia

NANCY DUDEK, MD, MEd

Associate Professor, Department of Medicine, Division
of Physical Medicine and Rehabilitation, University of
Ottawa, Ottawa, Ontario, Canada
Joint Contractures

ISRAEL DUDKIEWICZ, MD

Orthopaedic Surgeon, Consultant in Physical Medicine and
Rehabilitation, Tel Aviv, Israel
Cervical Spondylotic Myelopathy
Cervical Degenerative Disease

SHEILA DUGAN, MD

Associate Professor, Physical Medicine and Rehabilitation,
Rush Medical College, Chicago, Illinois
Ulnar Collateral Ligament Sprain
Stress Fractures of the Lower Limb

BLESSEN C. EAPEN, MD

Section Chief, Polytrauma Rehabilitation Center,
South Texas Veterans Health Care System; Assistant
Professor, Department of Rehabilitation Medicine,
University of Texas Health Science Center,
San Antonio, Texas
Deep Venous Thrombosis

JENNIFER L. EARLE, MD

Physical Medicine and Rehabilitation, Spaulding
Rehabilitation Hospital, Harvard Medical School,
Boston, Massachusetts
Lumbar Spondylolysis and Spondylolisthesis

GEROLD R. EBENBICHLER, MD

Physical Medicine and Rehabilitation, Vienna Medical
University, General Hospital of Vienna, Vienna, Austria
Chronic Fatigue Syndrome

RACHEL EGYHAZI, MD

Clinical Fellow, Pain Medicine, Department of
Anesthesiology, Massachusetts General Hospital,
Harvard Medical School, Boston, Massachusetts
Cervical Spinal Stenosis

OMAR EL ABD, MD

Assistant Professor, Physical Medicine and Rehabilitation,
Harvard Medical School, Boston, Massachusetts
Low Back Strain or Sprain

JEFFREY B. ELIASON, MD

Assistant Professor, Physical Medicine and Rehabilitation
Department, Emory University; Veterans Affairs
Medical Center, Atlanta, Georgia
Heterotopic Ossification

MAURY ELLENBERG, MD

Clinical Professor, Physical Medicine and Rehabilitation,
Wayne State University School of Medicine, Detroit,
Michigan
Lumbar Radiculopathy

MICHAEL J. ELLENBERG, MD

Rehabilitation Physicians PC, Novi, Michigan
Lumbar Radiculopathy

JESSE D. ENNIS, MD, FRCP(C)

Physical Medicine and Rehabilitation, Neurorehabilitation
Unit, Victoria General Hospital, Victoria, British
Columbia, Canada
Spinal Cord Injury (Thoracic)

ERIK ENSRUD, MD

Department of Neurology, Brigham and Women's
Hospital, Boston, Massachusetts
Myopathies
Plexopathy—Brachial

STEPHAN M. ESSER, MD

Physical Medicine and Rehabilitation, Heekin Orthopedics,
Jacksonville, Florida
Chronic Ankle Instability

AVITAL FAST, MD

Chief, Rehabilitation Medicine, Tel Aviv Sourasky
Medical Center, Tel Aviv, Israel; Professor Emeritus,
Albert Einstein College of Medicine, Bronx, New York
Cervical Spondylotic Myelopathy
Cervical Degenerative Disease

RICHARD FEENEY, DO

University of California Davis Medical Center,
Sacramento, California
Sacroiliac Joint Dysfunction

JEFFERY B. FELDMAN, PhD

Section of Neuropsychology, Department of Neurology;
Director, Center for Integrative Medicine; Associate,
Translational Science Institute;
Director, Occupational Rehabilitation Programs,
Wake Forest University, Winston-Salem,
North Carolina
Myofascial Pain Syndrome

JONATHAN T. FINNOFF, DO

Physician, Tahoe Orthopedics and Sports Medicine, South
Lake Tahoe, California; Clinical Professor, Department
of Physical Medicine and Rehabilitation, University
of California Davis School of Medicine, Sacramento,
California
Suprascapular Neuropathy
Hip Labral Tears

LESLIE S. FOSTER, DO

Parkway Neuroscience and Spine Institute,
Hagerstown, Maryland
Plantar Fasciitis

PATRICK M. FOYE, MD

Interim Chair and Associate Professor, Physical Medicine and Rehabilitation, Rutgers New Jersey Medical School, Newark, New Jersey
Hip Osteoarthritis

MICHAEL FREDERICSON, MD

Professor, Orthopedic Surgery and Physical Medicine and Rehabilitation; Director, Physical Medicine and Rehabilitation Sports Medicine, Stanford University Medical Center, Palo Alto, California
Greater Trochanteric Pain Syndrome

JOEL E. FRONTERA, MD

Assistant Professor, Department of Physical Medicine and Rehabilitation, University of Texas Medical School at Houston (UTHealth), Houston, Texas
Spasticity

WALTER R. FRONTERA, MD, PhD

Professor and Chair (inaugural), Department of Physical Medicine and Rehabilitation, Vanderbilt University School of Medicine; Medical Director of Rehabilitation Services, Vanderbilt University Medical Center, Nashville, Tennessee; Adjunct Professor, Department of Physiology, University of Puerto Rico School of Medicine, San Juan, Puerto Rico

MICHELLE GITTLER, MD

Residency Program Director, Associate Medical Director for Academic Affairs, Schwab Rehabilitation Hospital; Clinical Associate Professor of Surgery, Orthopedic Surgery, and Rehabilitation Medicine, University of Chicago, Chicago, Illinois
Lower Limb Amputations

MEL B. GLENN, MD

Director, Outpatient and Community Brain Injury Rehabilitation, Spaulding Rehabilitation Hospital; Associate Professor, Department of Physical Medicine and Rehabilitation, Harvard Medical School, Boston, Massachusetts; Medical Director, NeuroRestorative-Massachusetts, Braintree, Massachusetts; Medical Director, Community Rehab Care, Newton and Medford, Massachusetts
Postconcussion Symptoms

PETER GONZALEZ, MD

Associate Professor, Department of Physical Medicine and Rehabilitation, Eastern Virginia Medical School, Norfolk, Virginia
Iliotibial Band Syndrome

MARLÍ GONZÁLEZ-FERNÁNDEZ, MD, PhD

Assistant Professor, Physical Medicine and Rehabilitation, Johns Hopkins University School of Medicine; Medical Director Outpatient Clinics, Physical Medicine and Rehabilitation, Johns Hopkins Hospital, Baltimore, Maryland
Cerebral Palsy

THOMAS E. GROOMES, MD

Vanderbilt University Medical Center and Vanderbilt Stallworth Rehabilitation Hospital, Nashville, Tennessee
Total Knee Replacement

DAWN M. GROSSER, MD

Orthopaedic Surgeon, South Texas Bone and Joint, Corpus Christi, Texas
Ankle Arthritis
Bunion and Bunionette
Hallux Rigidus
Posterior Tibial Tendon Dysfunction

H. MICHAEL GUO, MD, PhD

Assistant Professor, Director, Neurorehabilitation Fellowship Program, Section of Physical Medicine and Rehabilitation, Department of Neurology, Wake Forest University School of Medicine, Winston Salem, North Carolina
Myofascial Pain Syndrome

NAVNEET GUPTA, MD

Johnson City, Tennessee
Knee Bursitis

HOPE S. HACKER, MD

Chief, Physical Medicine and Rehabilitation Services, Central Texas Veterans Health Care Systems, Temple, Texas
Plexopathy—Lumbosacral

LORI HALL, PT, MS, CLT-LANA

Physical Medicine and Rehabilitation Department, Parkland Health and Hospital System, Dallas, Texas
Lymphedema

ED HANADA, MD

Assistant Professor, Department of Medicine, Dalhousie University; Staff Physiatrist, Department of Medicine/Division of Physical Medicine and Rehabilitation, Capital District Health Authority, Halifax, Nova Scotia, Canada
Knee Bursitis

TONI J. HANSON, MD

Assistant Professor, Physical Medicine and Rehabilitation, Mayo Clinic, College of Medicine, Rochester, Minnesota
Thoracic Compression Fracture

AMANDA L. HARRINGTON, MD

Assistant Professor, Physical Medicine and Rehabilitation, University of Pittsburgh School of Medicine; Program Director, Spinal Cord Injury Medicine Fellowship, University of Pittsburgh Medical Center; Director of Spinal Cord Injury Services, University of Pittsburgh Medical Center Rehabilitation Institute, Pittsburgh, Pennsylvania
Heterotopic Ossification

DAVID E. HARTIGAN, MD

Department of Orthopedic Surgery, Mayo Clinic, Rochester, Minnesota
Labral Tears of the Shoulder

SETH D. HERMAN, MD

Physiatrist, Brain Injury Rehabilitation Program, Spaulding Rehabilitation Hospital; Associate Program Director, Neurological Rehabilitation Fellowship, Harvard Medical School/Spaulding Rehabilitation Hospital; Instructor, Department of Physical Medicine and Rehabilitation, Harvard Medical School, Boston, Massachusetts

Postconcussion Symptoms**JOSEPH E. HERRERA, DO**

Residency Program Director, Rehabilitation Medicine; Fellowship Director, Interventional Spine and Sports Medicine Division, Department of Rehabilitation; Director of Sports Medicine, Icahn School of Medicine at Mount Sinai Department of Rehabilitation Medicine, New York, New York

Compartment Syndrome of the Leg**CHESTER H. HO, MD**

Associate Professor and Head, Division of Physical Medicine and Rehabilitation, Department of Clinical Neurosciences and Hotchkiss Brain Institute, University of Calgary, Calgary, Alberta, Canada

Pressure Ulcers**ANNE Z. HOCH, DO**

Professor, Department of Orthopedic Surgery, Director, Women's Sports Medicine Program and Fellowship, Medical College of Wisconsin, Milwaukee, Wisconsin

Hamstring Strain**JASON HOLM, MD**

Twin Cities Orthopedics, Burnsville, Minnesota

Suprascapular Neuropathy**ALICE J. HON, MD**

Department of Physical Medicine and Rehabilitation, Rutgers New Jersey Medical School, Newark, New Jersey

Central Post-Stroke Pain (Thalamic Pain Syndrome)**THOMAS H. HUDGINS, MD**

Associate Division Head, Division of Physical Medicine and Rehabilitation, NorthShore University HealthSystem; Assistant Professor, Department of Orthopedics, University of Chicago, Pritzker School of Medicine, Chicago, Illinois

Cervical Sprain or Strain**Piriformis Syndrome****Patellar Tendinopathy (Jumper's Knee)****Patellofemoral Syndrome****Foot and Ankle Bursitis****KATARZYNA IBANEZ, MD**

Assistant Attending Physiatrist, Department of Neurology, Rehabilitation Service, Memorial Sloan Kettering Cancer Center; Assistant Professor of Rehabilitation Medicine, Weill Cornell Medical College, New York, New York

Radiation Fibrosis Syndrome**MAHMUD M. IBRAHIM, MD**

Fellow, Interventional Spine and Sports Medicine Division, Department of Rehabilitation, Icahn School of Medicine at Mount Sinai Department of Rehabilitation Medicine, New York, New York

Compartment Syndrome of the Leg**MARTA IMAMURA, MD**

Affiliated Professor and Chief of Staff, Technical Session, Division of Physical Medicine and Rehabilitation, Department of Orthopaedics and Traumatology; Coordinator, Clinical Research Center at the Institute of Physical and Rehabilitation Medicine, University of São Paulo School of Medicine, São Paulo, Brazil

Costosternal Syndrome**Tietze Syndrome****SATIKO T. IMAMURA, MD**

Professor, Division of Rehabilitation Medicine, Clinics Hospital, University of São Paulo School of Medicine, São Paulo, Brazil

Tietze Syndrome**ZACHARIA ISAAC, MD**

Director, Interventional Physical Medicine and Rehabilitation, Harvard Medical School; Medical Director, Comprehensive Spine Care Center, Brigham and Women's Hospital, Boston, Massachusetts

Lumbar Spinal Stenosis**Sacroiliac Joint Dysfunction****RATHI L. JOSEPH, DO**

Sports Medicine Fellow, Department of Sports Medicine and Family Medicine, Advocate Lutheran General Hospital, Park Ridge, Illinois

Piriformis Syndrome**Patellar Tendinopathy (Jumper's Knee)****Patellofemoral Syndrome****Foot and Ankle Bursitis****SHIVANG JOSHI, MD, MPH, BPharm**

Neurologist, New England Regional Headache Center, University of Massachusetts Medical School, Worcester, Massachusetts

Headaches**NANETTE C. JOYCE, DO, MAS**

Assistant Professor, Physical Medicine and Rehabilitation, University of California, Davis, Sacramento, California

Motor Neuron Disease**SE HEE JUNG, MD, PhD**

Department of Rehabilitation Medicine, Seoul National University Boramae Medical Center, Seoul, South Korea

Phantom Limb Pain**JONATHAN KAY, MD**

Professor of Medicine, Director of Clinical Research, Division of Rheumatology, University of Massachusetts Medical School and UMass Memorial Medical Center

Hand Rheumatoid Arthritis

AYAL M. KAYNAN, MD, FACS

Director, Minimally Invasive and Robotic Surgery;
Vice-Chairman, Section of Urology, Department of Surgery,
Morristown Medical Center, Morristown, New Jersey
Neurogenic Bladder

JOHN C. KEEL, MD

Department of Physical Medicine and Rehabilitation,
Harvard Medical School; The Spine Center,
New England Baptist Hospital, Boston, Massachusetts
Lumbar Spondylolysis and Spondylolisthesis

ROBERT KENT, DO, MHA, MPH

Pain Spine Sports Physiatry at the Kent Clinic,
Orlando, Florida
Temporomandibular Joint Dysfunction
Polytrauma Rehabilitation

FLORIAN S. KEPLINGER, MD

Rehab Medical Associates of Arkansas, Sherwood, Arkansas
Knee Bursitis

STUART KIGNER, DPM

Attending Staff, Podiatry Service, Massachusetts General
Hospital; Attending Staff, Podiatry Division, Brigham
and Women's Hospital, Boston, Massachusetts
Metatarsalgia

TODD A. KILE, MD

Consultant, Department of Orthopedic Surgery, Mayo
Clinic, Scottsdale, Arizona; Assistant Professor, Mayo
Clinic College of Medicine, Rochester, Minnesota
Ankle Arthritis
Bunion and Bunionette
Hallux Rigidus
Posterior Tibial Tendon Dysfunction

JOHN C. KING, MD

Professor, Rehabilitation Medicine, University of Texas
Health Science Center; Medical Director, Reeves
Rehabilitation Center, University Health System, San
Antonio, Texas
Peroneal Neuropathy
Plexopathy—Brachial
Plexopathy—Lumbosacral

NEIL KIRSCHBAUM, DO

Physical Medicine and Rehabilitation Residency Program,
Morsani College of Medicine, University of South
Florida, Tampa, Florida
Polytrauma Rehabilitation

MELISSA A. KLAUSMEYER, MD

Hand Surgery Fellow, Department of Orthopedics,
Division of Hand and Upper Extremity, Harvard
Medical School, Boston, Massachusetts
Wrist Rheumatoid Arthritis

JASON H. KORTTE, MS, CCC-SLP

Speech-Language Pathologist, Medstar Good Samaritan
Hospital; Affiliate Faculty, Loyola University, Baltimore,
Maryland
Speech and Language Disorders

BRIAN J. KRABAK, MD, MBA, FACSM

Clinical Associate Professor, Rehabilitation, Orthopedics,
and Sports Medicine, University of Washington and
Seattle Children's Sports Medicine, Seattle,
Washington

Adhesive Capsulitis
Biceps Tendinopathy
Ankle Sprain

GAIL LATLIEF, DO

Physical Medicine and Rehabilitation Service, James
A. Haley Veterans' Hospital; Assistant Professor,
Department of Neurology, Division of Physical
Medicine and Rehabilitation, Morsani College of
Medicine, University of South Florida, Tampa, Florida
Polytrauma Rehabilitation

SAMMY M. LEE, DPM

Attending Staff, Podiatry Service, Massachusetts General
Hospital, Boston, Massachusetts
Morton Neuroma

SHI-UK LEE, MD, PhD

Department of Rehabilitation Medicine, Seoul National
University College of Medicine; Department of Physical
Medicine and Rehabilitation, Seoul National University
Borame Medical Center, Seoul, Korea
Cervical Dystonia

TED A. LENNARD, MD

Clinical Assistant Professor, Department of Physical
Medicine and Rehabilitation, University of Arkansas
for Medical Sciences, Little Rock, Arkansas; Medical
Director, WorkComplete CoxHealthCare Systems,
Springfield Neurological and Spine Institute, Springfield,
Missouri
Cervical Facet Arthropathy
Lumbar Facet Arthropathy

PAUL LENTO, MD

Associate Professor, Physical Medicine and Rehabilitation,
Temple University School of Medicine, Philadelphia,
Pennsylvania
Collateral Ligament Sprain
Iliotibial Band Syndrome
Meniscal Injuries

JAN LEXELL, MD, PhD

Professor of Rehabilitation Medicine, Department of
Health Sciences, Lund University; Medical Director and
Consultant Physician, Department of Neurology and
Rehabilitation Medicine, Skåne University Hospital in
Lund, Lund, Sweden
Postpoliomyelitis Syndrome

PETER A.C. LIM, MD

Clinical Professor, Physical Medicine and Rehabilitation,
Baylor College of Medicine, Houston, Texas; Adjunct
Associate Professor, Medicine, Duke-National
University of Singapore Graduate Medical School;
Senior Consultant, Rehabilitation Medicine, Singapore
General Hospital, Singapore
Transverse Myelitis

CINDY LIN, MD

Attending Physician, Sports Medicine and Rehabilitation
Medicine, Sports Medicine Department, Changi
General Hospital, Singapore
Greater Trochanteric Pain Syndrome

KARL-AUGUST LINDGREN, MD, PhD

ORTON Rehabilitation Centre, Helsinki, Finland
Thoracic Outlet Syndrome

VASILIOS A. LIROFONIS, DPM

Attending Staff, Podiatry Service, Massachusetts General
Hospital, Boston, Massachusetts
Mallet Toe

ELIZABETH LODER, MD

Chief, Division of Headache and Pain, Department of
Neurology, Brigham and Women's Hospital, Boston,
Massachusetts
Headaches

EDRICK LOPEZ, MD, JD

Harvard Medical School, Department of Physical Medicine
and Rehabilitation, Spaulding Rehabilitation Hospital,
Boston, Massachusetts
Lumbar Spinal Stenosis

GERARD A. MALANGA, MD

New Jersey Sports Medicine, LLC, Cedar Knolls,
New Jersey; Clinical Professor, Physical Medicine and
Rehabilitation, University of Medicine and Dentistry of
New Jersey–New Jersey Medical School, Newark,
New Jersey
Rotator Cuff Tendinopathy
Rotator Cuff Tear

JULIE MARTIN, PT

Lead Outpatient Physical Therapist, James A. Haley
Veterans' Hospital, Tampa, Florida
Temporomandibular Joint Dysfunction

RAFAEL MASCARINAS, MD

Attending Physician, Physical Medicine and Rehabilitation
Service, James A. Haley Veterans' Hospital; Assistant
Professor, Department of Neurology, Division of
Physical Medicine and Rehabilitation, Morsani College
of Medicine, University of South Florida, Tampa,
Florida
Polytrauma Rehabilitation

JILL MASSENGALE, MS, ARNP

Physical Medicine and Rehabilitation Service, James A.
Haley Veterans' Hospital, Tampa, Florida
Temporomandibular Joint Dysfunction
Polytrauma Rehabilitation

KOICHIRO MATSUO, DDS, PhD

Professor, Department of Dentistry, School of Medicine,
Fujita Health University, Aichi, Japan
Dysphagia

MARISSA McCARTHY, MD

Assistant Professor, Department of Neurology, Division of
Physical Medicine and Rehabilitation, Morsani College
of Medicine, University of South Florida; Medical
Director, Traumatic Brain Injury/Polytrauma Unit,
James A. Haley Veterans' Hospital, Tampa, Florida
Temporomandibular Joint Dysfunction
Polytrauma Rehabilitation

KELLY C. McINNIS, DO

Instructor, Physical Medicine and Rehabilitation, Harvard
Medical School; Clinical Associate, Physical Medicine
and Rehabilitation, Massachusetts General Hospital,
Boston, Massachusetts
Repetitive Strain Injuries

PETER M. McINTOSH, MD

Assistant Professor, College of Medicine, Mayo Clinic,
Rochester, Minnesota; Consultant, Department of
Physical Medicine and Rehabilitation, Mayo Clinic,
Jacksonville, Florida
Scapular Winging
Adhesive Capsulitis of the Hip

ALEC L. MELEGER, MD

Assistant Professor of Physical Medicine and
Rehabilitation, Harvard Medical School, Boston,
Massachusetts; Medical Director, Spaulding Outpatient
Center, Medford, Massachusetts
Cervical Spinal Stenosis

BRYAN MERRITT, MD

Physical Medicine and Rehabilitation Service, James
A. Haley Veterans' Hospital; Assistant Professor,
Department of Neurology, Division of Physical
Medicine and Rehabilitation, Morsani College of
Medicine, University of South Florida, Tampa, Florida
Polytrauma Rehabilitation

LYLE J. MICHELI, MD

Program Director, Sports Medicine, Harvard University,
Boston, Massachusetts
Posterior Cruciate Ligament Sprain
Quadriceps Tendinopathy and Tendinitis

WILLIAM MICHEO, MD

Professor and Chairman, Physical Medicine and
Rehabilitation and Sports Medicine Department; Sports
Medicine Program Director, University of Puerto Rico,
San Juan, Puerto Rico
Glenohumeral Instability
Anterior Cruciate Ligament Tear

MATTHEW E. MILLER, MD

Captain, United States Army Medical Corps; Residency
Associate Program Director and Staff Physiatrist,
Physical Medicine and Rehabilitation, Walter
Reed National Military Medical Center, Bethesda,
Maryland
Plantar Fasciitis

GERARDO MIRANDA, MD

Assistant Professor, Physical Medicine and Rehabilitation and Sports Medicine, San Juan, Puerto Rico
Glenohumeral Instability

NATHAN MOHR, BA

Pre-medical Student, University of Northern Iowa, Cedar Falls, Iowa
Cervical Sprain or Strain

DANIEL P. MONTERO, MD

Mayo Clinic Florida, Jacksonville, Florida
Hammer Toe

S. JIT MOOKERJEE, DO

Physical Medicine and Rehabilitation Service, James A. Haley Veterans' Hospital; Assistant Professor, Department of Neurology, Division of Physical Medicine and Rehabilitation, Morsani College of Medicine, University of South Florida, Tampa, Florida
Polytrauma Rehabilitation

ALI MOSTOUFI, MD, FAAPMR, FAAPM

Assistant Professor, Physical Medicine and Rehabilitation, Tufts University; Medical Director, Boston Spine Center, Boston, Massachusetts
Cervical Radiculopathy
Chronic Pain Syndrome

CHAITANYA S. MUDGAL, MD, MS (Orth), MCh (Orth)

Chief and Director, Hand Fellowship Program, Orthopaedic Hand Service, Massachusetts General Hospital, Boston, Massachusetts
Wrist Osteoarthritis
Wrist Rheumatoid Arthritis

LARRY V. NAJERA III, MD

Schwab Rehabilitation Hospital, Chicago, Illinois; Pain Treatment Centers of Illinois, Orland Park, Illinois
Cervical Sprain or Strain

SHANKER NESATHURAI, MD, MPH, FRCP(C)

Professor of Medicine and Division Director of Physical Medicine and Rehabilitation, Michael G. DeGroote School of Medicine, McMaster University; Chief of Physical Medicine and Rehabilitation, Hamilton Health Sciences and St. Joseph's Healthcare, Hamilton, Ontario, Canada; Lecturer in Physical Medicine and Rehabilitation, Harvard Medical School, Spaulding Hospital, Boston, Massachusetts
Spinal Cord Injury (Thoracic)

JESS NORDIN, DO

Resident, Johns Hopkins Department of Physical Medicine and Rehabilitation, Baltimore, Maryland
Neural Tube Defects

CARINA J. O'NEILL, DO

Physical Medicine and Rehabilitation, Spaulding Rehabilitation, Braintree, Massachusetts; Clinical Instructor, Physical Medicine and Rehabilitation, Harvard Medical School, Boston, Massachusetts
de Quervain Tenosynovitis

ANDREA K. ORIGENES

Pre-medical Student, University of Illinois, Chicago, Illinois
Cervical Sprain or Strain

CEDRIC J. ORTIGUERA, MD

Consultant, Department of Orthopedics, Mayo Clinic, Jacksonville, Florida; Assistant Professor, Mayo Clinic, College of Medicine, Rochester, Minnesota
Labral Tears of the Shoulder

MICHAEL D. OSBORNE, MD

Assistant Professor, Physical Medicine and Rehabilitation, Mayo Clinic, Jacksonville, Florida
Chronic Ankle Instability
Arachnoiditis

JEFFREY B. PALMER, MD

Lawrence Cardinal Shehan Professor and Chair, Department of Physical Medicine and Rehabilitation; Professor, Physical Medicine and Rehabilitation, Otolaryngology–Head and Neck Surgery, and Functional Anatomy and Evolution; Johns Hopkins University; Psychiatrist-in-Chief, Department of Physical Medicine and Rehabilitation, Johns Hopkins Hospital; Chair, Department of Physical Medicine and Rehabilitation, Medstar Good Samaritan Hospital, Baltimore, Maryland
Dysphagia
Speech and Language Disorders

PAUL F. PASQUINA, MD

United States Army Medical Corps (Colonel Ret.); Residency Director and Chair, Physical Medicine and Rehabilitation, Uniformed Services University of the Health Sciences, Walter Reed National Military Medical Center, Bethesda, Maryland
Plantar Fasciitis

ATUL T. PATEL, MD, MHSA

Kansas City Bone and Joint Clinic, Overland Park, Kansas; Medical Director of Adult Program, Rehabilitation Institute of Kansas City; Adjunct Associate Professor, Physical Therapy, University of Kansas Medical Center, Kansas City, Kansas
Trapezius Strain
Pubalgia

JOSEMARIA PATERNO, MD

Fellow, Interventional Pain, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Trigeminal Neuralgia

INDER PERKASH, MD, FRCS, FACS

Professor of Urology (emeritus), Paralyzed Veterans of America Professor of Spinal Cord Injury Medicine (emeritus), Professor of Medicine (Gastrointestinal) and Physical Medicine and Rehabilitation, Stanford University, Stanford, California
Neurogenic Bladder
Neurogenic Bowel

EDWARD M. PHILLIPS, MD

Assistant Professor of Physical Medicine and Rehabilitation; Director and Founder, Institute of Lifestyle Medicine, Joslin Diabetes Center, Harvard Medical School; Adjunct Scientist, United States Department of Agriculture, Jean Mayer Human Nutrition Research Center on Aging, Tufts University, Boston, Massachusetts
Knee Osteoarthritis
Osteoarthritis

DANIEL C. PIMENTEL, MD

Interventional Physiatrist, Director of Spine Center HCor; Assistant Professor, University of São Paulo, School of Medicine, São Paulo, Brazil
Thoracic Radiculopathy
Thoracic Sprain or Strain

THOMAS E. POBRE, MD

Director of Outpatient Services, Physical Medicine and Rehabilitation, Nassau University Medical Center, East Meadow, New York
Radial Neuropathy

REBECCA POSTHUMA, MD

Clinical Research Fellow, Female Pelvic and Reconstructive Surgery, Massachusetts General Hospital, Boston, Massachusetts
Pelvic Pain

ALISON R. PUTNAM, DO

Department of Physical Medicine and Rehabilitation, Virginia Mason Medical Center, Seattle, Washington
Iliotibial Band Syndrome

JAMES RAINVILLE, MD

Assistant Clinical Professor, Physical Medicine and Rehabilitation, Harvard Medical School; Chief, Physical Medicine and Rehabilitation, Orthopedics, New England Baptist Hospital, Boston, Massachusetts
Lumbar Spondylolysis and Spondylolisthesis

V.S. RAMACHANDRAN, MD, PhD

Professor, Department of Psychology, University of California, San Diego, California
Complex Regional Pain Syndrome

DAVID RING, MD, PhD

Associate Professor of Orthopaedic Surgery, Harvard Medical School, Chief of Hand Surgery, Massachusetts General Hospital, Boston, Massachusetts
Hand Osteoarthritis
Hand Rheumatoid Arthritis

JUSTIN RIUTTA, MD, FAAPMR

Department of Physical Medicine and Rehabilitation, William Beaumont Hospital, Royal Oak, Michigan
Post-Mastectomy Pain Syndrome
Post-Thoracotomy Pain Syndrome

ALEXANDRA RIVERA-VEGA, MD

Assistant Professor, Department of Physical Medicine and Rehabilitation at University of Arkansas for Medical Sciences, Little Rock, Arkansas
Glenohumeral Instability

THOMAS D. RIZZO, JR., MD

Consultant, Department of Physical Medicine and Rehabilitation, Mayo Clinic, Jacksonville, Florida; Assistant Professor, Physical Medicine and Rehabilitation, Mayo Clinic College of Medicine, Rochester, Minnesota
Acromioclavicular Injuries

DARREN ROSENBERG, DO

Assistant Professor, Physical Medicine and Rehabilitation, Harvard Medical School, Boston, Massachusetts
Thoracic Radiculopathy
Thoracic Sprain or Strain
Baker Cyst

SEWARD B. RUTKOV, MD

Professor, Neurology, Harvard Medical School/Beth Israel Deaconess Medical Center, Boston, Massachusetts
Peripheral Neuropathies

SUNIL SABHARWAL, MD

Assistant Professor, Department of Physical Medicine and Rehabilitation, Harvard Medical School; Chief, Spinal Cord Injury, Veterans Affairs Boston Health Care System, Boston, Massachusetts
Spinal Cord Injury (Cervical)
Spinal Cord Injury (Lumbosacral)

FRANCISCO H. SANTIAGO, MD

Attending Physician, Physical Medicine and Rehabilitation, Bronx-Lebanon Hospital, Bronx, New York
Median Neuropathy
Ulnar Neuropathy (Wrist)

ROBERT J. SCARDINA, DPM

Chief, Podiatry Service; Residency Program Director, Podiatry Service, Massachusetts General Hospital; Instructor in Orthopaedic Surgery, Harvard Medical School, Boston, Massachusetts
Mallet Toe
Metatarsalgia
Morton Neuroma

MICHAEL K. SCHAUFLE, MD

Pain Solutions Treatment Centers, Marietta, Georgia
Lumbar Degenerative Disease

JEFFREY C. SCHNEIDER, MD

Medical Director, Trauma, Burn, and Orthopedic Program,
Spaulding Rehabilitation Hospital; Assistant Professor,
Physical Medicine and Rehabilitation, Harvard Medical
School, Boston, Massachusetts
Burns

STEVEN SCOTT, DO

Assistant Professor, Department of Neurology, Division
of Physical Medicine and Rehabilitation; Chief, Physical
Medicine and Rehabilitation, University of South
Florida, Tampa, Florida
Temporomandibular Joint Dysfunction
Polytrauma Rehabilitation

MICHAEL SEIN, MD

Department of Anesthesiology, University of California,
San Diego, San Diego, California
Knee Osteoarthritis

FERNANDO SEPÚLVEDA, MD

Chief Resident, Physical Medicine and Rehabilitation
Residency Training Program, University of Puerto Rico
School of Medicine, San Juan, Puerto Rico
Anterior Cruciate Ligament Tear

JOHN SERGENT, MD

Professor of Medicine, Division of Rheumatology,
Department of Internal Medicine, Vanderbilt University
Medical Center, Nashville, Tennessee
Systemic Lupus Erythematosus

VIVEK M. SHAH, MD

Clinical Instructor in Orthopaedic Surgery, New England
Baptist Hospital, Longwood Orthopedic Associates, Inc.,
Chestnut Hill, Massachusetts
Kienböck Disease

NUTAN SHARMA, MD, PhD

Associate Professor, Neurology, Harvard Medical School;
Associate Neurologist, Massachusetts General Hospital;
Associate Neurologist, Brigham and Women's Hospital,
Boston, Massachusetts
Parkinson Disease

HUMA SHEIKH, MD

Clinical Instructor, Brigham and Women's Hospital–
Neurology, Harvard Medical School, Boston,
Massachusetts
Headaches

SARAH SHUBERT, MD

Falmouth Orthopaedic Center, Falmouth, Maine
Olecranon Bursitis

IMRAN J. SIDDIQUI, MD

Department of Physical Medicine and Rehabilitation,
Spaulding Rehabilitation Hospital, Harvard Medical
School, Boston, Massachusetts
Lumbar Spondylolysis and Spondylolisthesis

JULIE K. SILVER, MD

Associate Professor, Department of Physical Medicine
and Rehabilitation, Harvard Medical School, Boston,
Massachusetts
Trigger Finger

KENNETH H. SILVER, MD

Department of Physical Medicine and Rehabilitation,
Johns Hopkins University School of Medicine;
Medstar Good Samaritan Hospital, Baltimore,
Maryland
Movement Disorders

ANEESH SINGLA, MD, MPH

Physician, National Spine and Pain Centers; Medical
Director, Rockville, Maryland; Lecturer, Harvard
Medical School, Boston, Massachusetts
Occipital Neuralgia
Trigeminal Neuralgia

MICHAEL SLESINSKI, DO

Instructor, Department of Physical Medicine and
Rehabilitation, Michigan State University–College of
Osteopathic Medicine, East Lansing,
Michigan
Quadriceps Contusion

DAVID M. SLOVIK, MD

Associate Professor of Medicine, Harvard Medical
School, Boston, Massachusetts; Chief, Division
of Endocrinology, Newton-Wellesley Hospital,
Newton, Massachusetts; Physician, Endocrine
Unit, Massachusetts General Hospital, Boston,
Massachusetts
Osteoporosis

KURT SPINDLER, MD

Vanderbilt Orthopaedic Institute, Nashville,
Tennessee
Knee Chondral Injuries

JOSEPH STANDLEY, DO

Physical Medicine and Rehabilitation Service,
James A. Haley Veterans' Hospital, Tampa, Florida
Polytrauma Rehabilitation

JOEL STEIN, MD

Simon Baruch Professor and Chair, Rehabilitation and
Regenerative Medicine, Columbia University
College of Physicians and Surgeons; Professor and
Chief, Division of Rehabilitation Medicine,
Weill Cornell Medical College; Physiatrist-in-Chief,
New York–Presbyterian Hospital, New York,
New York
Stroke

SONJA K. STILP, MD

Boulder, Colorado
Iliotibial Band Syndrome

TODD P. STITIK, MD

Professor, Physical Medicine and Rehabilitation;
Director, Occupational/Musculoskeletal Medicine,
Rutgers New Jersey Medical School, Newark,
New Jersey

Hip Osteoarthritis

MICHAEL F. STRETANSKI, DO

Medical Director/Fellowship Director, Interventional
Spine and Pain Rehabilitation Center, Mansfield, Ohio;
Spine and Pain Services Director, Wyandot Memorial
Hospital, Upper Sandusky, Ohio; Full Professor,
Rehabilitation Medicine, Pain Medicine, Ohio University
College of Osteopathic Medicine, Columbus, Ohio

Biceps Tendon Rupture

Shoulder Arthritis

Dupuytren Contracture

Shin Splints

Achilles Tendinopathy

MICHAEL D. STUBBLEFIELD, MD

Associate Attending Psychiatrist and Chief, Rehabilitation
Service, Department of Neurology, Memorial
Sloan Kettering Cancer Center; Associate Professor of
Rehabilitation Medicine, Weill Cornell Medical College,
New York, New York

Radiation Fibrosis Syndrome

JORDAN L. TATE, MD, MPH

Physical Medicine and Rehabilitation, Emory University,
Atlanta, Georgia

Lumbar Degenerative Disease

MAYA THERATTIL, MD

Assistant Professor, Clinical Rehabilitation Medicine,
Albert Einstein College of Medicine, Bronx,
New York

Scoliosis and Kyphosis

ANN-MARIE THOMAS, MD, PT

Assistant Professor, Physical Medicine and
Rehabilitation, Harvard Medical School; Staff
Physiatrist, Physical Medicine and Rehabilitation,
Spaulding Rehabilitation Hospital; Clinical
Associate, Physical Medicine and Rehabilitation,
Massachusetts General Hospital; Associate Physiatrist
in Medicine, Brigham and Women's Hospital, Boston,
Massachusetts

Multiple Sclerosis

MARK A. THOMAS, MD

Associate Professor, Physical Medicine and
Rehabilitation, Albert Einstein College of
Medicine; Program Director, Physical Medicine and
Rehabilitation, Montefiore Medical Center, Bronx,
New York

Scoliosis and Kyphosis

JIAXIN TRAN, MD

Rutgers New Jersey Medical School, Newark, New Jersey

Complex Regional Pain Syndrome

GUY TRUDEL, MD, MSc, FRCPC, DABPMR

Professor of Medicine, Surgery, and Biochemistry, Faculty
of Medicine, University of Ottawa, Ottawa, Ontario,
Canada

Joint Contractures

TONY URBISCI, BS

Morsani College of Medicine, University of South Florida,
Tampa, Florida

Temporomandibular Joint Dysfunction

SATHYA VADIVELU, DO

Fellow, Pediatric Rehabilitation Medicine, Kennedy
Krieger Institute, Physical Medicine and Rehabilitation,
Johns Hopkins University, Baltimore, Maryland

Cerebral Palsy

RAMON VALLARINO, JR., MD

Attending Physician, Department of Neurosciences,
New York Methodist Hospital, Brooklyn, New York;
Clinical Assistant Professor, Department of Physical
Medicine and Rehabilitation, Albert Einstein College
of Medicine of Yeshiva University, Bronx,
New York

Median Neuropathy

Ulnar Neuropathy (Wrist)

MONICA VERDUZCO-GUTIERREZ, MD

Assistant Professor, Department of Physical Medicine and
Rehabilitation, University of Texas Medical School at
Houston (UTHealth), Houston, Texas

Spasticity

ARIANA VORA, MD

Instructor, Physical Medicine and Rehabilitation,
Harvard Medical School; Staff Physiatrist,
Massachusetts General Hospital; Staff Physiatrist,
Spaulding Rehabilitation Hospital, Boston,
Massachusetts

Coccydynia

Postherpetic Neuralgia

ADAM WALLACE, MD

Pain Management of Tulsa, Tulsa, Oklahoma

Arachnoiditis

BETH M. WEINMAN, DO

Sports Medicine Fellow, Department of Orthopedic
Surgery, Medical College of Wisconsin, Milwaukee,
Wisconsin

Hamstring Strain

JAY M. WEISS, MD

Medical Director, Long Island Physical Medicine and
Rehabilitation, Jericho, New York

Lateral Epicondylitis

Medial Epicondylitis

Ulnar Neuropathy (Elbow)

LYN D. WEISS, MD

Chairman and Program Director, Physical Medicine and Rehabilitation, Nassau University Medical Center, East Meadow, New York

Lateral Epicondylitis
Medial Epicondylitis
Radial Neuropathy
Ulnar Neuropathy (Elbow)

DAVID WEXLER, MD, FRCS (Tr & Orth)

Orthopaedic Surgeon, Center for Joint Replacement, St. Mary's Regional Medical Center, Lewiston, Maine

Ankle Arthritis
Bunion and Bunions
Hallux Rigidus
Posterior Tibial Tendon Dysfunction

JANE WIERBICKY, RN, BSN

National Spinal Cord Injury Association, Gloucester, Massachusetts

Spinal Cord Injury (Thoracic)

J. MICHAEL WIETING, DO, MEd, FAOCPRM, FAAPMR

Interim Dean; Associate Dean, Clinical Medicine; and Assistant Vice President, New Program Development, DeBusk College of Medicine/Division of Health Sciences; Professor of Physical Medicine and Rehabilitation; Professor of Osteopathic Manipulative Medicine, Lincoln Memorial University–DeBusk College of Osteopathic Medicine, Harrogate, Tennessee

Quadriceps Contusion

ALLEN N. WILKINS, MD

Assistant Professor of Clinical Rehabilitation and Regenerative Medicine, Weill Cornell Medical College; Associate Medical Director, Manhattan Physical Medicine and Rehabilitation, LLP, New York, New York

Knee Osteoarthritis
Osteoarthritis

FAREN H. WILLIAMS, MD, MS

Chief and Clinical Professor, Physical Medicine and Rehabilitation Division, Department of Physical Rehabilitation and Orthopedics, University of Massachusetts Medical School, Worcester, Massachusetts

Rheumatoid Arthritis

AMY X. YIN, MD

Resident Physician, Physical Medicine and Rehabilitation, Harvard Medical School/Spaulding Rehabilitation Hospital, Boston, Massachusetts

Coccydynia
Postherpetic Neuralgia
Burns
Osteoarthritis

MARK YOUNG, MD

Massachusetts General Hospital, Boston, Massachusetts

Occipital Neuralgia

MEIJUAN ZHAO, MD

Instructor, Physical Medicine and Rehabilitation, Harvard Medical School; Staff Physiatrist, Spaulding Rehabilitation Hospital, Massachusetts General Hospital, Boston, Massachusetts

Median Neuropathy (Carpal Tunnel Syndrome)

Preface

When the first edition of this work was created, we wanted to publish a book that covered a variety of medical conditions that any physiatrist, internist, family physician, orthopedist, rheumatologist, or neurologist could encounter in his or her medical practice. We particularly wanted to emphasize the clinical aspects of both musculoskeletal injuries and chronic medical conditions requiring rehabilitation from the perspective of a practitioner in an ambulatory setting. In the second edition we maintained the structure of the book and added an entirely new section on the ambulatory management of pain conditions.

This, the third edition of *Essentials of Physical Medicine and Rehabilitation*, again covers many diagnoses in a deliberately succinct and specific format. The first section contains 94 chapters on specific musculoskeletal diagnoses, conveniently organized by anatomic region. The second section describes the management of pain conditions in 23 specific conditions. The third section covers 45 common medical conditions that are typically chronic and benefit from long-term rehabilitative interventions. Although some of these conditions require hospitalization, we have tried to focus on the rehabilitation that takes place in an ambulatory setting. The content of the third edition includes new topics such as labral tears (shoulder and hip) and conditions associated with cancer and its treatment. Each chapter includes the same sections in the same order (Synonyms, ICD-9 Codes, new ICD-10 Codes, Definition, Symptoms, Physical Examination,

Functional Limitations, Diagnostic Studies, Differential Diagnosis, Treatment [Initial, Rehabilitation, Procedures, and Surgery], Potential Disease Complications, Potential Treatment Complications, and References). In this edition we are including both the ICD-9 and ICD-10 codes. The new ICD-10 codes allow for greater specificity in describing a patient's diagnosis, and we hope that they will help busy clinicians in their practices.

It is our hope that physicians in all specialties and allied health care providers will find that this book complements the excellent existing rehabilitation textbooks and that it will be an efficient and useful reference tool in the office setting.

We are extremely grateful for the hard work of our colleagues who authored these chapters and who represent many different specialties and come from excellent institutions. Their generous support of our work has made this book possible.

Finally, we would like to thank our editorial team at Elsevier. Their assistance was invaluable in bringing this book to publication. Anne Snyder, our senior content development specialist, deserves special recognition for her commitment to this project.

Walter R. Frontera, MD, PhD

Contents

PART 1

MUSCULOSKELETAL DISORDERS

SECTION I

Head, Neck, and Upper Back.....3

- 1 Cervical Spondylotic Myelopathy 3
Avital Fast and Israel Dudkiewicz
- 2 Cervical Facet Arthropathy 8
Ted A. Lennard
- 3 Cervical Degenerative Disease 12
Avital Fast and Israel Dudkiewicz
- 4 Cervical Dystonia..... 17
Moon Suk Bang and Shi-Uk Lee
- 5 Cervical Radiculopathy 22
Ali Mostoufi
- 6 Cervical Sprain or Strain 31
Larry V. Najera III, Joseph T. Alleva, Nathan Mohr,
Andrea K. Origenes, and Thomas H. Hudgins
- 7 Cervical Spinal Stenosis 35
Alec L. Meleger and Rachel Eghazi
- 8 Cervicogenic Vertigo 40
Joanne Borg-Stein and Melissa Colbert
- 9 Trapezius Strain 43
Atul T. Patel

SECTION II

Shoulder.....46

- 10 Acromioclavicular Injuries 46
Thomas D. Rizzo, Jr.
- 11 Adhesive Capsulitis 53
Brian J. Krabak
- 12 Biceps Tendinopathy 58
Brian J. Krabak
- 13 Biceps Tendon Rupture..... 62
Michael F. Stretanski
- 14 Glenohumeral Instability..... 66
William Micheo, Alexandra Rivera-Vega, and
Gerardo Miranda

- 15 Labral Tears of the Shoulder 73
David E. Hartigan and Cedric J. Ortiguera
- 16 Rotator Cuff Tendinopathy 80
Jay E. Bowen and Gerard A. Malanga
- 17 Rotator Cuff Tear 85
Jay E. Bowen and Gerard A. Malanga
- 18 Scapular Winging 90
Peter M. McIntosh
- 19 Shoulder Arthritis 97
Michael F. Stretanski
- 20 Suprascapular Neuropathy 103
Jason Holm and Jonathan T. Finnoff

SECTION III

Elbow and Forearm.....107

- 21 Elbow Arthritis..... 107
Charles Cassidy and Chien Chow
- 22 Lateral Epicondylitis..... 113
Lyn D. Weiss and Jay M. Weiss
- 23 Medial Epicondylitis..... 116
Lyn D. Weiss and Jay M. Weiss
- 24 Median Neuropathy 119
Francisco H. Santiago and Ramon Vallarino, Jr.
- 25 Olecranon Bursitis 125
Charles Cassidy and Sarah Shubert
- 26 Radial Neuropathy..... 129
Lyn D. Weiss and Thomas E. Pobre
- 27 Ulnar Neuropathy (Elbow)..... 133
Lyn D. Weiss and Jay M. Weiss

SECTION IV

Hand and Wrist.....136

- 28 de Quervain Tenosynovitis..... 136
Carina J. O'Neill
- 29 Dupuytren Contracture 140
Michael F. Stretanski
- 30 Extensor Tendon Injuries..... 145
Jeffrey S. Brault

31	Flexor Tendon Injuries	151
	Jeffrey S. Brault	
32	Hand and Wrist Ganglia.....	155
	Charles Cassidy and Victor Chung	
33	Hand Osteoarthritis	160
	David Ring	
34	Hand Rheumatoid Arthritis	165
	David Ring and Jonathan Kay	
35	Kienböck Disease.....	169
	Charles Cassidy and Vivek M. Shah	
36	Median Neuropathy (Carpal Tunnel Syndrome)	174
	Meijuan Zhao and David T. Burke	
37	Trigger Finger	180
	Keith A. Bengtson and Julie K. Silver	
38	Ulnar Collateral Ligament Sprain	184
	Sheila Dugan and Sol M. Abreu Sosa	
39	Ulnar Neuropathy (Wrist)	188
	Ramon Vallarino, Jr., and Francisco H. Santiago	
40	Wrist Osteoarthritis.....	194
	Anna Babushkina and Chaitanya S. Mudgal	
41	Wrist Rheumatoid Arthritis	203
	Melissa A. Klausmeyer and Chaitanya S. Mudgal	

SECTION V

Mid Back.....211

42	Thoracic Compression Fracture.....	211
	Toni J. Hanson	
43	Thoracic Radiculopathy	217
	Darren Rosenberg and Daniel C. Pimentel	
44	Thoracic Sprain or Strain	221
	Darren Rosenberg and Daniel C. Pimentel	

SECTION VI

Low Back

45	Lumbar Degenerative Disease.....	225
	Michael K. Schaufele and Jordan L. Tate	
46	Lumbar Facet Arthropathy.....	233
	Ted A. Lennard	
47	Lumbar Radiculopathy.....	237
	Maury Ellenberg and Michael J. Ellenberg	
48	Low Back Strain or Sprain	244
	Omar El Abd and Joao E.D. Amadera	

49	Lumbar Spondylolysis and Spondylolisthesis..	249
	Jennifer L. Earle, Imran J. Siddiqui, James Rainville, and John C. Keel	

50	Lumbar Spinal Stenosis.....	257
	Zacharia Isaac and Edrick Lopez	

51	Sacroiliac Joint Dysfunction	264
	Zacharia Isaac and Richard Feeney	

SECTION VII

Pelvis, Hip, and Thigh

52	Adhesive Capsulitis of the Hip.....	270
	Peter M. McIntosh	
53	Hip Adductor Strain.....	276
	Ricardo Colberg	
54	Femoral Neuropathy	281
	Earl J. Craig and Daniel M. Clinchot	
55	Hip Osteoarthritis	285
	Patrick M. Foye and Todd P. Stitik	
56	Hip Labral Tears.....	291
	Matthew M. Diesselhorst and Jonathan T. Finnoff	
57	Lateral Femoral Cutaneous Neuropathy.....	296
	Earl J. Craig and Daniel M. Clinchot	
58	Piriformis Syndrome	300
	Rathi L. Joseph, Joseph T. Alleva, and Thomas H. Hudgins	
59	Pubalgia	304
	Atul T. Patel	
60	Quadriceps Contusion	308
	J. Michael Wieting and Michael Slesinski	
61	Total Hip Replacement	312
	Juan A. Cabrera and Alison L. Cabrera	
62	Greater Trochanteric Pain Syndrome	320
	Michael Fredericson, Cindy Lin, and Kelvin Chew	

SECTION VIII

Knee and Leg

63	Anterior Cruciate Ligament Tear	324
	William Micheo, Eduardo Amy, and Fernando Sepúlveda	
64	Baker Cyst	331
	Darren Rosenberg and Joao E.D. Amadera	
65	Knee Chondral Injuries	335
	Alison L. Cabrera and Kurt Spindler	

66	Collateral Ligament Sprain.....	339	83	Ankle Sprain	426
	Paul Lento and Venu Akuthota			Brian J. Krabak	
67	Compartment Syndrome of the Leg	344	84	Bunion and Bunionette.....	431
	Joseph E. Herrera and Mahmud M. Ibrahim			David Wexler, Dawn M. Grosser, and Todd A. Kile	
68	Hamstring Strain	350	85	Chronic Ankle Instability.....	435
	Omar M. Bhatti, Beth M. Weinman, and Anne Z. Hoch			Michael D. Osborne and Stephan M. Esser	
69	Iliotibial Band Syndrome.....	355	86	Foot and Ankle Bursitis	439
	Venu Akuthota, Sonja K. Stilp, Paul Lento, Peter Gonzalez, and Alison R. Putnam			Rathi L. Joseph and Thomas H. Hudgins	
70	Knee Osteoarthritis.....	361	87	Hallux Rigidus	445
	Michael Sein, Allen N. Wilkins, and Edward M. Phillips			David Wexler, Dawn M. Grosser, and Todd A. Kile	
71	Knee Bursitis.....	369	88	Hammer Toe	448
	Ed Hanada, Florian S. Keplinger, and Navneet Gupta			Daniel P. Montero	
72	Meniscal Injuries.....	373	89	Mallet Toe	452
	Paul Lento and Venu Akuthota			Vasilios A. Lirofonis and Robert J. Scardina	
73	Patellar Tendinopathy (Jumper's Knee)	380	90	Metatarsalgia.....	455
	Rathi L. Joseph, Joseph T. Alleva, and Thomas H. Hudgins			Stuart Kigner and Robert J. Scardina	
74	Patellofemoral Syndrome.....	384	91	Morton Neuroma	459
	Rathi L. Joseph, Joseph T. Alleva, and Thomas H. Hudgins			Sammy M. Lee and Robert J. Scardina	
75	Peroneal Neuropathy.....	389	92	Plantar Fasciitis	463
	John C. King			Paul F. Pasquina, Leslie S. Foster, and Matthew E. Miller	
76	Posterior Cruciate Ligament Sprain.....	394	93	Posterior Tibial Tendon Dysfunction.....	468
	Farshad Adib, Christine Curtis, Peter Bienkowski, and Lyle J. Micheli			David Wexler, Todd A. Kile, and Dawn M. Grosser	
77	Quadriceps Tendinopathy and Tendinitis	399	94	Tibial Neuropathy (Tarsal Tunnel Syndrome)	471
	Farshad Adib, Christine Curtis, Peter Bienkowski, and Lyle J. Micheli			David R. Del Toro	
78	Shin Splints	401			
	Michael F. Stretanski				
79	Stress Fractures of the Lower Limb.....	405			
	Sheila Dugan and Sol M. Abreu Sosa				
80	Total Knee Replacement	411			
	Thomas E. Groomes				
SECTION IX			PART 2		
Foot and Ankle.....			PAIN		
		419	95	Arachnoiditis	477
81	Achilles Tendinopathy.....	419		Michael D. Osborne and Adam Wallace	
	Michael F. Stretanski		96	Chemotherapy-Induced Peripheral Neuropathy	482
82	Ankle Arthritis.....	423		Maryam R. Aghalar and Christian M. Custodio	
	David Wexler, Dawn M. Grosser, and Todd A. Kile		97	Chronic Pain Syndrome.....	485
				Ali Mostoufi	
			98	Coccydynia	490
				Ariana Vora and Amy X. Yin	
			99	Complex Regional Pain Syndrome.....	495
				Jiaxin Tran, V.S. Ramachandran, and Eric L. Altschuler	
			100	Costosternal Syndrome	501
				Marta Imamura and David A. Cassius	

101 Fibromyalgia 505 Melissa Colbert and Joanne Borg-Stein	120 Ankylosing Spondylitis..... 609 George W. Deimel IV and Steven E. Braverman
102 Headaches..... 509 Huma Sheikh, Shivang Joshi, and Elizabeth Loder	121 Burns..... 614 Jeffrey C. Schneider and Amy X. Yin
103 Intercostal Neuralgia 514 Susan J. Dreyer and William J. Beckworth	122 Cardiac Rehabilitation..... 622 Alan M. Davis
104 Myofascial Pain Syndrome..... 520 Martin K. Childers, Jeffery B. Feldman, and H. Michael Guo	123 Cancer-Related Fatigue..... 628 Andrea Cheville
105 Occipital Neuralgia..... 527 Mark Young and Aneesh Singla	124 Cerebral Palsy..... 634 Sathya Vadivelu and Marlís González-Fernández
106 Pelvic Pain 533 Rebecca Posthuma and Allison Bailey	125 Chronic Fatigue Syndrome 642 Gerold R. Ebenbichler
107 Phantom Limb Pain 540 Moon Suk Bang and Se Hee Jung	126 Joint Contractures 648 Mark Campbell, Nancy Dudek, and Guy Trudel

M54.13 Cervicothoracic radiculitis

Definition

Cervical spondylotic myelopathy (CSM) is a frequently encountered entity in middle-aged and elderly patients. The condition affects both men and women. Progressive degeneration of the cervical spine involves the discs, facet joints, joints of Luschka, ligamenta flava, and laminae, leading to gradual encroachment on the spinal canal and spinal cord compromise. CSM has a fairly typical clinical presentation and, frequently, a progressive and disabling course.

As a consequence of aging, the spinal column goes through a cascade of degenerative changes that tend to affect selective regions of the spine. The cervical spine is affected in most adults, most frequently at the C4-C7 region [1,2]. Degeneration of the intervertebral discs triggers a cascade of biochemical and biomechanical changes, leading to decreased disc height, among other changes. As a result, abnormal load distribution in the motion segments causes cervical spondylosis (i.e., facet arthropathy) and neural foraminal narrowing. Disc degeneration also leads to the development of herniations (soft discs), disc calcification, posteriorly directed bone ridges (hard discs), hypertrophy of the facets and the uncinate joints, and ligamenta flava thickening. On occasion, more frequently in Asians but not infrequently in white individuals, the posterior longitudinal ligament and the ligamenta flava ossify [3]. These degenerative changes narrow the dimensions

and change the shape of the cervical spinal canal. In normal adults, the anteroposterior diameter of the subaxial cervical spinal canal measures 17 to 18mm, whereas the spinal cord diameter in the same dimension is about 10mm. Severe CSM gradually decreases the space available for the cord and brings about cord compression in the anterior-posterior axis. Cord compression usually occurs at the discal levels [4–6].

The encroaching structures may also compress the anterior spinal artery, resulting in spinal cord ischemia that usually involves several cord segments beyond the actual compression site. Spinal cord changes in the form of demyelination, gliosis, myelomalacia, and eventually severe atrophy may develop [4,7–9]. Dynamic instability, which can be diagnosed in flexion or extension lateral x-ray views, further complicates matters. Disc degeneration leads to laxity of the supporting ligaments, bringing about anterolisthesis or retrolisthesis in flexion and extension, respectively. This may further compromise the spinal cord and intensify the presenting symptoms [2,4].

Symptoms

CSM develops gradually during a lengthy period of months to years. Not infrequently, the patient is unaware of any functional compromise, and the first person to notice that something is amiss may be a close family member. Whereas pain appears rather early in cervical radiculopathy and alerts the patient to the presence of a problem, this is usually not the case in CSM. A long history of neck discomfort and intermittent pain may frequently be obtained, but these are not prominent at the time of CSM presentation.

Most patients have a combination of upper motor neuron symptoms in the lower extremities and lower motor neuron symptoms in the upper extremities [4]. Patients frequently present with gait dysfunction resulting from a combination of factors, including ataxia due to impaired joint proprioception, hypertonicity, weakness, and muscle control deficiencies.

Studies have demonstrated that severely myelopathic patients display abnormalities of deep sensation, including vibration and joint position sense, which is attributed to compression of the posterior columns [10,11]. Paresthesias and numbness may be frequently mentioned. Compression of the pyramidal and extrapyramidal tracts can lead to spasticity, weakness, and abnormal muscle contractions. These sensory and motor deficits result in an unstable gait. Patients may complain of stiffness in the lower extremities or plain weakness manifesting as foot dragging and tripping [5]. Symptoms related to the upper extremities are mostly the result of fine motor coordination deficits. At times, the symptoms in the upper extremities are much more severe than those related to the lower extremities, attesting to central cord compromise [4]. Most patients do not have urinary symptoms. However, urinary symptoms (i.e., incontinence) may occasionally develop in patients with long-standing myelopathy [12]. As CSM develops in middle-aged and elderly patients, the urinary symptoms may be attributed to aging, comorbidities, and cord compression. Bowel incontinence is rare.

Physical Examination

Because of sensory ataxia, the patient may be observed walking with a wide-based gait. Some resort to a cane to

increase the base of support and to enhance safety during ambulation. Patients with severe gait dysfunction frequently require a walker and cannot ambulate without one. Many patients lose the ability to tandem walk. The Romberg test result may become positive. Examination of the lower extremities may reveal muscle atrophy, increased muscle tone, abnormal reflexes—clonus or upgoing toes (Babinski sign), and abnormalities of position and vibration sense. Muscle fasciculations may be observed. The foot tapping test (number of sole tapings while the heel maintains contact with the floor in 10 seconds) is an easy and useful quantitative tool for lower extremity function in these patients [13].

In the upper extremities, weakness and atrophy of the small muscles of the hands may be noted. The patient may have difficulties in fine motor coordination (e.g., unbuttoning the shirt or picking a coin off the table). The patient frequently displays difficulty in performing repetitive opening and closing of the fist. In normal individuals, 20 to 30 repetitions can be performed in 10 seconds.

Weakness can occasionally be documented in more proximal muscles and may appear symmetrically. Fasciculations may appear in the wasted muscles. Hypesthesia, paresthesia, or anesthesia may be documented. On occasion, the sensory findings in the hands are in a glove distribution. As in the lower extremities, the vibration and joint position senses may be disturbed. Hyporeflexia or hyperreflexia may be found. The Hoffmann response may become positive and can be facilitated in early myelopathy by cervical extension [14]. In some patients, severe atrophy of all the hand intrinsic muscles is observed [1,5,15,16].

The neck range of motion may be limited in all directions. Many patients cannot extend the neck beyond neutral and may feel electric-like sensation radiating down the torso on neck flexion, known as the Lhermitte sign. Often, when a patient stands against the wall, the back of the head stays an inch to several inches away, and the patient is unable to push the head backward to bring it to touch the wall.

Functional Limitations

Patients with CSM have difficulties with activities of daily living. Patients may have difficulties inserting keys, picking up coins, buttoning a shirt, or manipulating small objects. Handwriting may deteriorate. Patients may drop things from the hands and occasionally can complain of numbness affecting the fingers or the palms, mimicking peripheral neuropathy [2,5,15,17,18]. They may have problems dressing and undressing. When weakness is a predominant feature, they will be unable to carry heavy objects. Unassisted ambulation may become difficult. The gait is slowed and becomes inefficient. In late stages of CSM, patients may become almost totally disabled and require assistance with most activities of daily living.

Diagnostic Studies

Plain radiographs usually reveal multilevel degenerative disc disease with cervical spondylosis. Dynamic studies (flexion and extension views) may reveal segmental instability with anterolisthesis on flexion and retrolisthesis on extension. In patients with ossification of the posterior longitudinal ligament, the ossified ligament may be detected on lateral plain

films. The Torg-Pavlov ratio may help diagnose congenital spinal stenosis. This ratio can be obtained on plain films by dividing the anteroposterior diameter of the vertebral body by the anteroposterior diameter of the spinal canal at that level. The canal diameter can be measured from the posterior wall of the vertebra to the spinolaminar line [19]. A ratio of 0.8 and below is indicative of spinal stenosis (Fig. 1.1) [20].

Magnetic resonance imaging, the study of choice, provides critical information about the extent of stenosis and the condition of the compressed spinal cord. Sagittal and axial cuts clearly show the offending structures (discs, thickened ligamenta flava), and the cord shape and signal provide critical information about the extent of cord compression and the prognosis (Fig. 1.2). Increased cord signal on T2-weighted images is abnormal and points to the presence of edema, demyelination, myelomalacia, or gliosis. Decreased cord signal on T1-weighted images may also be observed. However, these cord signal changes are of limited value in predicting functional outcome. A newer magnetic resonance imaging technique, diffusion tensor imaging of the cervical cord, holds considerable promise in predicting the severity of cord injury and may help guide the clinician in deciding whether to operate because it may show cord abnormalities before the development of T2 hyperintensity on conventional sequences [21,22]. Severe cord atrophy denotes a poor prognosis even when decompressive surgery is performed.

FIGURE 1.1 Schematic lateral view of the cervical spine. The canal diameter (A) can be measured by drawing a line between the posterior border of the vertebral body and the spinolaminar line. The vertebral diameter is reflected by line B. (From Fast A, Goldsher D. *Navigating the Adult Spine*. New York, Demos Medical Publishing, 2007.)

FIGURE 1.2 Sagittal T2-weighted image of the cervical spine showing degenerative disc disease involving the C4-5 and C5-6 intervertebral discs.

Computed tomographic myelography provides fine and detailed information on the amount and location of neural compression and is frequently obtained before surgery. Electrodiagnostic studies play an important role, especially in diabetic patients with peripheral neuropathy, which may confound the clinical diagnosis.

Differential Diagnosis

- Amyotrophic lateral sclerosis
- Multifocal motor neuropathy [23]
- Multiple sclerosis
- Syringomyelia
- Peripheral neuropathy

Treatment

Initial

The treatment of CSM depends on the stage in which it is discovered. No conservative treatment can be expected to decompress the spinal cord. In the initial stages, education of the patient is of paramount importance. The patient is instructed to avoid cervical spinal hyperextension. As the cervical spinal canal diameter decreases and the spinal cord diameter increases during cervical hyperextension, this position may lead to further cord compression [24]. The patient is advised to drink with a straw and to avoid prolonged overhead activities.

Rehabilitation

Because the course of CSM may be unpredictable and a significant percentage of patients deteriorate in a slow stepwise

course, close monitoring of the patient's neurologic condition and spine is indicated. Patients with mild CSM may be managed conservatively. A biannual detailed neurologic examination and an annual magnetic resonance imaging evaluation are indicated. Special attention should be devoted to the cord cross-sectional area and the cord signal; these are important prognostic factors and may help determine whether surgery is indicated. In the interim, patients should be instructed in *static* neck exercises. Weak muscles in the upper or lower extremities should be strengthened with progressive resistance exercise techniques. Judicial use of anti-inflammatory medications is called for, especially in elderly individuals. Soft cervical collars are frequently used (recommended by physicians or obtained by patients without the physician's recommendations) without a sound scientific basis. Assistive devices, such as a cane or walker, should be provided when ambulation safety is compromised.

Procedures

No existing procedures affect the course or symptoms of cervical myelopathy.

Surgery

Patients with moderate to severe progressive CSM (unsteady gait, limited function in the upper extremities) who have significant cord compression or cord signal changes should be referred for decompressive surgery. Two main approaches exist—anterior and posterior.

Anterior Approach

The anterior approach is usually reserved for patients with myelopathy affecting up to three spinal levels. This approach allows adequate decompression of “anterior” disease. Anterior disease refers to pathologic changes that are anterior to the spinal cord (e.g., soft disc, hard disc, vertebral body spurs, and ossified posterior longitudinal ligament). Through this approach, the offending structures can be removed without disturbing the spinal cord. The anterior approach allows adequate decompression in patients with cervical kyphotic deformity. After anterior decompression (anterior cervical decompression and fusion, corpectomies), bone grafting and instrumentation ensure stabilization and fusion. This approach is not indicated in patients whose predominant pathologic process is posterior to the cord (i.e., hypertrophied ligamentum flavum) or in patients with disease affecting more than three or four segments because this may lead to an increased rate of complications, including pseudarthrosis [6,16].

Posterior Approach

The posterior approach consists of two basic procedures, laminectomy and laminoplasty.

Cervical laminectomy can be easily performed by most spinal surgeons and is less technically demanding than anterior corpectomies are. This approach allows easy access to posterior disease, such as hypertrophied laminae and ligamenta flava. The main disadvantage of the laminectomy procedure is that it requires stripping of the paraspinal muscles and thus tends to destabilize the cervical spine. This may result in loss of the cervical lordosis or frank kyphotic

deformity and instability (stepladder deformity), especially when it is performed over several spinal levels or when the facet joints have to be sacrificed.

Laminoplasty, another procedure performed through the posterior approach, has been developed in Japan and addresses some of the shortcomings of laminectomy. Unlike laminectomy, cervical laminoplasty preserves the cervical facets and the laminae. In this procedure, the laminae are hinged away (lifted by an osteotomy) from the site of main pathologic change, resulting in an increase of sagittal canal diameter [25]. Unilateral or bilateral hinges can be performed; the bilateral hinge approach allows symmetric expansion of the spinal canal. It is hoped that after posterior decompression, the spinal cord will “migrate” away from the anterior pathologic process, and thus cord decompression will be achieved [16,26]. This has been confirmed in magnetic resonance imaging studies after laminoplasty.

Regardless of the surgical approach, poor outcome and higher complication rate can be expected in elderly patients with long-standing myelopathy and spinal cord atrophy [27].

Potential Disease Complications

Left untreated, a patient with progressive myelopathy may develop severe disability. Patients may become totally dependent and nonambulatory. In some cases, neurogenic bladder may develop and further compromise the quality of life.

Potential Treatment Complications

Pseudarthrosis, restenosis, spinal instability, postoperative radiculopathy, kyphotic deformity, and axial pain are among the surgical complications [14].

CHAPTER 2

Cervical Facet Arthropathy

Ted A. Lennard, MD

Synonyms

Facet joint arthritis
Apophyseal joint pain
Spondylosis
Z-joint pain
Zygapophyseal joint pain
Posterior element disorder

ICD-9 Codes

715.1 Osteoarthritis, localized, primary
715.2 Osteoarthritis, localized, secondary
719.4 Pain in joint
721.0 Cervical spondylosis without myelopathy
723.1 Cervicalgia
723.3 Cervicobrachial syndrome
723.9 Unspecified musculoskeletal disorders and symptoms referable to neck
847.0 Neck: atlanto-occipital (joints), atlantoaxial (joints), whiplash injury

ICD-10 Codes

M43.02 Cervical spondylosis
M54.2 Cervicalgia
S13.4 Neck: Sprain of atlanto-axial (joints), sprain of atlanto-occipital (joints), whiplash injury

Definition

Cervical facet joints are located in the posterior portion of the cervical spine (Fig. 2.1). These paired synovial joints allow mobility and provide stability to the head and neck. Each of these joints is innervated by the medial branch of the posterior primary ramus [1–3]. Cervical facet arthropathy refers to any acquired, degenerative, or traumatic process that affects the normal function of

the facet joints in the cervical region, often resulting in a source of neck pain and cervicogenic headaches. It may be a primary source of pain (e.g., after a whiplash injury) but often is secondary to a degenerative or injured cervical disc, fracture, or ligamentous injury. Common causes of cervical facet pain include acceleration-deceleration cervical injuries (whiplash), a sudden torque motion to the head and neck with extension and rotation, and a cervical compression force. In some cases, simply looking upward may cause facet pain. The cervical facet joints may also become painful in conjunction with a cervical disc herniation, after a cervical discectomy or fusion, or after a cervical compression fracture.

Cervical facet arthrosis appears to increase with age and occurs more commonly in the upper cervical spine. In cadaveric studies, the prevalence of cervical arthrosis was greatest for the C4-C5 level, followed by the C3-C4 level [4]. The C6-C7 level was least involved. Abnormal findings within the cervical facet joints appear to be independent of race and gender [5].

Symptoms

Patients typically complain of generalized posterior neck and suboccipital pain but may present with localized tenderness over the posterolateral aspect of the neck. Pain provoked with cervical extension and axial rotation is common. These joints may refer pain anywhere from the midthoracic spine to the cranium and often in the suboccipital region [6–8]. Neurologic symptoms, such as sensory complaints and muscle weakness in the upper limbs, are not expected in patients with primary cervical facet pain. Concomitant nerve root or cord injury is more likely if these symptoms are present.

Physical Examination

The essential element of the examination is manual palpation of the spinal segments and elicitation of reproducible pain over the involved joints [9]. Localized point tenderness over the cervical paraspinal muscles is common and is precipitated by excessive cervical lordosis, causing abnormal joint forces. The fluidity of motion of the involved spinal area—cervical region may suggest extension pain with relief on flexion. Patients may present with loss of cervical motion

FIGURE 2.1 Lateral fluoroscopic view of the right C2-3 zygapophyseal joint with the needle tip inside the joint. (From Dreyfuss P, Kaplan M, Dreyer SJ. *Zygapophyseal joint injection techniques in the spinal axis*. In Lennard TA, ed. *Pain Procedures in Clinical Practice*, 3rd ed. Philadelphia, Elsevier/Saunders, 2011: 373.)

and paraspinal spasms. Unless cervical disc or nerve root disease is also present, the findings of the neurologic examination are otherwise typically normal.

Functional Limitations

Cervical extension and rotation, overhead lifting, and overhead reaching may be difficult when the cervical spine is involved. This may interfere with activities such as bathing, grooming, and driving.

Diagnostic Studies

Fluoroscopically guided intra-articular arthrography confirmed that anesthetic injections are the “gold standard” for diagnosis (Fig. 2.2) [10–13]. Abnormalities detected on radiography, computed tomography, or magnetic resonance imaging have not been shown to correlate with facet joint pain. A single-photon emission computed tomographic scan can be used in refractory cases of suspected cervical facet disorders to rule out underlying bone processes that may mimic facet pain (e.g., spondylolysis, infection, tumor) [14]. When an abnormality is detected, the scan may confirm the proposed diagnosis and determine which specific joint is affected.

FIGURE 2.2 Lateral radiograph of a C2-3 Z-joint arthrogram by a lateral approach. (From Dreyfuss P, Kaplan M, Dreyer SJ. *Zygapophyseal joint injection techniques in the spinal axis*. In Lennard TA, ed. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000:291.)

Differential Diagnosis

- Degenerative disc disease
- Myofascial pain syndrome
- Internal disc disruption
- Disc herniation
- Cervical stenosis
- Nerve root compression
- Spondylolysis, spondylolisthesis
- Osteoid osteoma
- Tumor
- Infection

Treatment

Initial

Initial treatment emphasizes local pain control with ice, stretching, nonsteroidal anti-inflammatory drugs and oral analgesics, topical creams, transcutaneous electrical nerve stimulation, local periarticular corticosteroid injections, and avoidance of exacerbating activities [15]. Specialized pillows may be helpful, but rarely are cervical collars indicated.

Rehabilitation

Manual forms of therapy (e.g., myofascial release, muscle energy, soft tissue mobilization, and strain-counterstrain techniques) and low-velocity manipulations (e.g., osteopathic manipulation) are commonly used for isolated facet disorders, but their effectiveness has been questioned [16,17]. In healthy patients with no associated spinal disease (e.g., disc abnormalities, stenosis, radiculopathy, fracture), low-velocity manipulations may be used on a limited basis in cases unresponsive to routine conservative care [18–20]. Use in the

cervical region should be approached with extreme caution and performed only by experienced practitioners.

Physical therapy may consist of passive modalities such as electrical stimulation, ultrasound, and traction to reduce local pain. However, these modalities have not been shown to change long-term outcomes [18–21]. Regional manual therapy with facet gapping techniques can be helpful. Advancement into a flexion-biased exercise program with regional stretching is the mainstay of rehabilitation. Cervical exercises include both static and dynamic resisted forward and lateral flexion movements. Following cervical facet injections, passive modalities, stretching, and exercises can be useful to reduce pain and to maximize functional recovery. For recurrent episodes of pain, a change in daily and work activity or in sporting technique and other biomechanical adjustments may eliminate the underlying forces at the joint level.

Procedures

Intra-articular, fluoroscopically guided, contrast-enhanced facet injections are considered critical for proper diagnosis and can be instrumental in the treatment of facet joint arthropathies [22,23]. Ultrasound guidance for facet injections is gaining in popularity [24,25]. A patient can be examined both before and after injection to determine what portion of his or her pain can be attributed to the joints injected. Typically, small amounts of anesthetic or corticosteroid are injected directly into the joint. Another step may be to perform medial branch blocks of the affected joints with small volumes (0.1 to 0.3 mL) of anesthetic. If the facet joint is found to be the putative source of pain, a denervation procedure by use of radiofrequency, cryotherapy, or chemicals (e.g., phenol) may be considered [26,27]. Acupuncture may also be considered [28].

Surgery

Surgery is rarely necessary in isolated facet joint arthropathies. Surgical spinal fusion may be performed for discogenic pain, which may affect secondary cases of facet joint arthropathies.

Potential Disease Complications

Because facet joint arthropathy is usually degenerative in nature, this disorder is often progressive, resulting in chronic, intractable spinal pain. It usually coexists with spinal disc abnormalities, further leading to chronic pain. This subsequently results in diminished spinal motion, weakness, and loss of flexibility.

Potential Treatment Complications

Treatment-related complications may be caused by medications; analgesics may cause constipation or liver dysfunction, and nonsteroidal anti-inflammatory drugs may cause gastrointestinal and renal problems. Local periarticular injections and acupuncture may cause local transient needle pain. Facet injections may cause transient local spinal pain, swelling, and possibly bruising. More serious injection complications may include infection, injury to a blood vessel or nerve, injury to

the spinal cord, and allergic reaction to the medications [13]. Fortunately, major complications are rare [29]. Exacerbation of symptoms often transiently occurs after injection. Cervical injections may also precipitate headaches.

M54.2 Cervical Pain

Definition

The term *cervical degenerative disease* encompasses a wide range of pathologic changes affecting all the components of the cervical spine that may lead to axial or radicular pain.

The mechanisms underlying cervical degenerative disease are complex and multifactorial. Genetics, aging, and attrition and trauma may all play an important role. It is believed that disc degeneration results in altered, abnormal load distribution, which in turn leads to a cascade of structural changes that affect the various components of the spinal column. These structural changes may change spinal posture and stability and may compromise neural function. The pathomechanisms underlying axial and radicular pain are still not completely clear. Increased vascularization after discal herniation and the presence of inflammatory mediators such as nitric oxide, prostaglandin E₂, interleukin-6, matrix metalloproteinase, and others play an important role in the pathogenesis of pain [1].

In the seventh and eighth decades of life, most if not all individuals display diffuse degenerative changes throughout the cervical spine. Only a fraction of these individuals, however, have clinical signs and symptoms. Not uncommonly, individuals who are symptomatic early on become asymptomatic as the degenerative process evolves.

The lowest five cervical vertebrae are connected by five structural elements: the intervertebral disc, the facet joints, and the neurocentral joints (joints of Luschka) [2]. The neurocentral joints are unique to the cervical spine and do not appear anywhere else in the spinal column. These joints, located in the posterolateral aspect of the vertebral bodies, consist of bone projections that articulate with the vertebral body above them (Fig. 3.1). They provide some stability to the very mobile cervical spine and protect the exiting nerve roots from pure lateral disc herniations. Once the disc degenerates, however, these joints may hypertrophy, narrow the intervertebral foramina, and modify their shape, thus compromising the radicular nerves or the dorsal root ganglia. A similar degenerative process may involve the facet joints that are posteriorly located, and they in turn

FIGURE 3.1 Schematic representation of the joint of Luschka in the coronal plane. (From Fast A, Goldsher D. *Navigating the Adult Spine*. New York, Demos Medical Publishing, 2007.)

may compress the exiting neural elements from the back. Indeed, the most common cause of cervical radiculopathy is foraminal narrowing due to facet or neurocentral joint hypertrophy [3]. The lower cervical spine, especially C4-C5, C5-C6, and to a lesser extent C6-C7, is the source of pain in most symptomatic individuals. Unlike in the lumbar spine, nucleus pulposus herniation is less frequent and is the cause of radicular pain in only 20% to 25% of cases [3,4]. As the spinal cord occupies a substantial proportion of the cervical spinal canal, posteriorly directed herniations can result in significant cord compression as well as radicular symptoms.

Symptoms

The most common symptom, one that drives most of the patients to the physician's office, is pain. In the general population, the point prevalence for neck pain ranges between 9.5% and 22%, whereas lifetime prevalence may be as high as 66%. The annual incidence is higher in men and peaks around 50 to 54 years of age [5,6].

In this respect, two large groups of patients can be recognized: patients whose main complaint is limited to axial pain and patients with radicular pain. Patients with axial pain typically complain of stiffness and pain in the cervical spine. The pain is usually more severe in the upright position and relieved only with bed rest. Cervical motion, especially hyperextension and side bending, increases the pain. In patients with pathologic changes involving the upper cervical joints or degeneration of upper cervical discs, the pain may radiate into the head, typically into the occipital region. In patients with lower cervical disease, the pain radiates into the region of the superior trapezius or the interscapular region. On occasion, patients present with atypical symptoms, such as jaw pain or chest pain—cervical angina.

Identification of the pain generator and its management are far more challenging in patients with axial pain because imaging studies frequently show multilevel pathologic changes, such as multilevel disc degeneration, facet arthropathy, and uncovertebral joint disease. It is often difficult and quite challenging to identify the exact source of pain. As the facets and the uncovertebral joints, peripheral discs, and ligaments all contain nerve endings, each one or a combination of them could be the source of pain [4].

Patients with radicular pain have symptoms commensurate with the involved nerve root. The pain usually follows a

myotomal distribution and is frequently described as boring, aching, deep-seated pain. The pain is made worse by tilting the head toward the affected side or by hyperextension and side bending. Infrequently, patients find that the pain may be made more tolerable when the hand of the symptomatic side is placed over the top of the head (shoulder abduction release) [7]. The sensory symptoms (numbness, tingling, and burning sensation) usually follow the dermatomal distribution. When carpal tunnel syndrome accompanies cervical radiculopathy (double crush syndrome), the sensory changes may be in median nerve distribution. Indeed, there is a high concurrent incidence of cervical radiculopathy and carpal tunnel syndrome [8]. Sclerotomal pain, frequently overlooked or interpreted as trigger points, may be present and commonly resides in the medial or lateral scapular borders [9,10]. On occasion, patients complain of arm or hand weakness as they may drop things or find difficulty with routine activities of daily living.

Physical Examination

Because of severe axial pain, the patient may keep the head and neck immobile as cervical movements may increase the symptoms. Frequently, the only comfortable position is when the patient reclines and the neck is unloaded. Axial pain may increase with cervical extension or side bending. The Spurling test, whereby simultaneous axial loading and tilting of the head toward the symptomatic side in the upright position are performed, elicits neck and radicular pain. This test may elicit a specific dermatomal pain pattern and has high specificity and sensitivity of 95% for identifying nerve root compression [11]. Manual neck distraction may alleviate the symptoms. Tender spots are frequently found over the cervical paraspinal muscles, within the superior trapezius muscles, or in muscles supplied by the compromised root. These spots refer to areas within the muscles that, when stimulated, elicit a sensation of local pain [10]. Tender spots may be of diagnostic significance, especially when they are found unilaterally or in conjunction with other symptoms of cervical radiculopathy.

In patients with radicular pain, depending on the root involved, examination may reveal weakness in myotomal distribution, sensory changes in dermatomal distribution, and reflex changes (Table 3.1). Meticulous physical examination helps identify the compromised root: C5 root compromise will affect shoulder abductors; C6, elbow flexors; C7, elbow extensors; and C8, finger flexors. Finding of concomitant sensory and reflex changes is helpful. Dermatome arrangement is not fixed and may vary in different patients because of aberrant rootlets or anastomoses between peripheral nerves. Frequently, dermatomes represent only a portion of the root's domain [12]. The dermatomal charts are useful, however, and play a role in the patient's diagnosis. Radicular pain frequently occurs without weakness, reflex, or apparent sensory changes. The most frequently affected roots are C5, C6, and C7 [3,6]. In the cervical region, unlike in other regions of the spine, the nerve roots exit the spine above their respective vertebrae; the C5 nerve root exits above C5 vertebra and hence may be compromised by herniation of the C4-5 intervertebral disc. The C8 nerve root exits below

Table 3.1 Salient Features of the Most Frequently Affected Roots

	Predominantly Affected Muscles	Sensory Distribution	Reflex Changes
C5	Deltoid, supraspinatus, and infraspinatus	Shoulder and lateral aspect of arm	Supinator reflex
C6	Elbow flexors: biceps brachialis, brachioradialis, and radial extensors of the wrist	Distal lateral forearm, thumb, and index fingers	Biceps reflex
C7	Triceps, wrist flexors	Dorsal aspects of forearm and middle finger	Triceps reflex
C8	Flexor digitorum superficialis and profundus	Ulnar aspects of forearm, hand, and fourth and fifth fingers	No reflex changes

the C7 vertebral body; all the subsequent nerves below that level follow the same pattern.

Looking for long tract signs is of paramount importance because their presence points toward cord compression and may modify the treatment plan. The diagnostic accuracy of the physical examination is fairly reliable and may correlate well with imaging studies [9,11,13,14].

Functional Limitations

The functional limitations associated with cervical degenerative disease depend on the extent of the degenerative changes and the neurologic involvement. Not infrequently, patients are asymptomatic, and the only functional limitation noted is loss of cervical range of motion. They tend to hold the neck in a forward stooped posture; the neck is held in forward flexion and cannot achieve extension. When these patients stand against a wall, the back of the head may be inches away from it, and they cannot straighten the cervical spine. These patients may function well but have limited range of motion in all planes and cannot look up. When weakness is present, patients may have functional deficits corresponding with their spinal level of involvement (e.g., patients with C8-T1 involvement may drop things and have difficulties with movements requiring fine motor coordination).

Diagnostic Studies

Radiographs (anteroposterior, lateral, oblique, and flexion and extension views) are frequently obtained but may be of limited use. The vertebral components are clearly seen in these studies but not the intervertebral discs, spinal cord, or peripheral nerves. The x-ray films clearly show degenerative changes (narrowing intervertebral discs; spurs and calcified or ossified soft tissues). Frequently, there is no good correlation between the symptoms and the extent of degenerative findings on radiographs [14]. Diffuse multilevel changes are frequently observed but are, for the most part, irrelevant to the patient's symptoms. Flexion and extension views are important as they can detect degenerative instability that is responsible for the symptoms and that may not be seen in the static views [6]. Radiographs are not helpful in the early stages of infection and tumors.

Magnetic resonance imaging is the diagnostic modality of choice because it allows visualization of the whole cervical spine without irradiation and enables the clinician to assess the neural structures (cord, roots) as well as the soft tissues (discs, ligaments). Correlation of the

FIGURE 3.2 Sagittal T2-weighted image of the cervical spine showing spinal cord compression at the C3-C4 and C4-C5 levels. At the C3-C4 level, the cord is compressed from the front and from the back. No cerebrospinal fluid is visible in the compressed regions.

imaging studies with the history and clinical examination is of utmost importance because in many individuals, the magnetic resonance imaging studies reveal significant pathologic changes (herniated discs, neural foraminal stenosis) that are totally irrelevant to the patient's complaints and symptoms (Fig. 3.2). Computed tomography should be obtained after trauma because it may identify fractures that could be otherwise missed on plain radiography and even magnetic resonance imaging studies. Computed tomographic myelography is frequently obtained before surgery but should not be obtained on a routine basis. Patients with axial pain who do not respond to conservative measures can be referred for discography to identify the pain generator. Discography may be the only way to identify the disc responsible for the symptoms; however, this procedure remains controversial and should be performed only in selected patients. Electrodiagnostic studies play an important role, especially in diabetic patients or whenever peripheral neuropathies are suspected [8,15].

Differential Diagnosis [16]

Rotator cuff tendinitis
Rotator cuff tear
Peripheral neuropathies
Carpal tunnel syndrome
Spine tumors
Spinal infection
Brachial plexopathy
Thoracic outlet syndrome

Treatment

Initial

The management of patients with axial pain without radicular symptoms is much more challenging than the management of radicular pain. In the case of axial pain, it is often difficult to identify the pain generator and thus to initiate a direct therapeutic response. Anti-inflammatory drugs along with analgesics should be prescribed as a first line of treatment in the initial stages of the disease. Patients with severe radicular pain may be managed with systemic steroids, such as methylprednisolone (Dosepak), when they do not respond to other anti-inflammatory drugs. Steroids may be beneficial in relieving pain because they reduce inflammation and swelling, thereby facilitating neural nutrient and blood supply, and stabilize neural membranes, thus suppressing ectopic discharges within the affected nerve fibers. They may be administered during the course of a week to 10 days in tapering dose. For severe pain, a starting dose of 70 mg of prednisone decreasing by 10 mg daily may be recommended. Methylprednisolone is quite handy, as the daily dose is prearranged separately within the package. A substantial percentage of patients with spondylotic radicular nontraumatic pain are expected to improve significantly after fluoroscopically guided therapeutic selective nerve root injections (see later) [17,18]. Patients with severe burning pain may respond favorably to gabapentin (Neurontin) or pregabalin (Lyrica).

The patient should be instructed to try the shoulder abduction release maneuver as a therapeutic measure (i.e., put the affected hand over the head) with the hope that this might decrease the tension on the affected nerve root and bring some symptomatic relief [19].

Rehabilitation

Conclusive high-quality studies that clearly define the most efficient rehabilitation approach to patients with neck pain are still lacking [5]. The more commonly applied methods are summarized here.

Activity modifications are of paramount importance. It has been demonstrated in vivo that the neural foraminal dimensions vary with flexion and extension. It has been shown that cervical flexion increases foraminal height, width, and cross-sectional area, whereas extension has the opposite effects [20,21]. Because foraminal narrowing plays a major clinical role in patients with cervical radicular pain, patients should be advised to avoid activities in which cervical extension is involved. The patients should be instructed to drink with a straw, to avoid overhead activities, to face the sink

while shampooing the hair, to adjust the monitor height, and the like. Temporary immobilization of the cervical spine may bring about some relief. This can be accomplished with a collar when the patient is mobile but should be used only temporarily. Cervical traction, provided it is administered in the supine position with the head held in slight flexion, may be of value in patients with radicular pain. Traction could be administered manually or, preferably, through a mechanized approach. The mechanized approach allows accurate traction forces to be administered. The distraction forces that are applied to the neck can, to some extent, relieve nerve compression by increasing the foraminal height and the intervertebral distance [22]. Traction application in the supine position is preferable because the weight of the head is eliminated and all the traction forces are effectively directed to the cervical spine. Despite its common use, no conclusive evidence that proves its therapeutic efficacy exists, however [23,24]. Superficial heat should be applied concomitantly with the traction as an adjunct therapy to relax the muscles before and during traction. Isometric neck exercises should be recommended as they may preserve muscle tone and strength without leading to pain. Cervical range of motion exercises are not recommended during the acute pain period.

Manual medicine (massage, mobilization, manipulation), acupuncture, and electrical stimulation are also widely used. Although these approaches are popular, studies demonstrating their efficacy are still lacking [25–32].

Procedures

Translaminar and transforaminal (selective nerve root) steroid administration may provide significant and at times long-term relief in patients with radicular pain. Properly selected, up to 60% of patients who are managed with selective nerve root injection may have good to excellent outcome [3,17]. Because there may be a significant risk with these injections (i.e., vertebral artery injury), they should be fluoroscopically guided and administered only by physicians with proper training.

Surgery

The main indications for surgery are severe or progressive neurologic deficits and persistent pain that does not respond to conservative measures.

The standard surgical treatment of cervical radiculopathy for many decades has been anterior cervical decompression and fusion. This approach prevailed because in most patients with cervical radiculopathy, the symptoms are caused by osteophytes compressing the nerves within the intervertebral foramina, and laminectomy is not effective in these cases.

The anterior approach permits excellent access to anteriorly impinging structures, such as discs and spondylotic spurs. Some surgeons add instrumentation (i.e., plate) to increase the fusion rate and the postoperative stability [13]. Adequate foraminal decompression can result in early pain relief and enhanced muscle strength. Long term, however, no significant differences in pain or function have been found between conservatively and surgically treated patients [25,33]. Dysphagia, which frequently follows the anterior approach, usually subsides several weeks postoperatively.

The negative long-term effects of fusion have only recently been appreciated. Fusion leads to stiffness and lost range of motion, and over the years, it results in next-level degeneration (i.e., accelerated discal degeneration above and below the fused vertebrae). This has led to the development of disc replacement surgery—arthroplasty. Whereas the concept of disc replacement is attractive as disc replacement maintains the intervertebral discal height while preserving spinal motion [34], the advantages of this approach and its long-term effects have not yet been established [35].

Patients with single-level soft disc herniation may be operated on from the back. In these patients, laminotomy with foraminotomy may bring about relief without fusion and its complications while maintaining cervical stability [13].

Potential Disease Complications

Chronic pain and permanent neurologic deficits may develop in some patients. These may compromise the quality of life and interfere with activities of daily living.

Potential Treatment Complications

Steroid administration carries certain risks, and these should be considered before steroid administration. Surgical complications include infection, nerve injury, pain, stiffness, pseudarthrosis, and next-level degeneration.

G24.1 Idiopathic torsion dystonia
G24.2 Symptomatic torsion dystonia

Definition

Idiopathic cervical dystonia, the most common form of adult-onset focal dystonia, is twisting and turning of the neck caused by abnormal involuntary muscle contractures [1]. Cervical dystonia has also been known as spasmodic torticollis, which implies head jerking or neck spasms. However, these features are absent in 25% to 35% of patients with this condition [2]. Furthermore, the term *spasmodic torticollis* fails to emphasize the dystonic nature of the condition and the frequent association of cervical dystonia with dystonia in adjacent or remote body parts.

The incidence of cervical dystonia has been estimated at 1.07 per 100,000 person-years [3]. Women are affected 1.5 to 1.9 times more often than men are [2,4]. In 70% to 90% of cases, the disease begins between the fourth and sixth decades, with a peak incidence in the fifth decade of life [5].

The pathogenetic mechanisms are unclear, but increasing evidence suggests that cervical dystonia is influenced by genetic factors. Many patients with cervical dystonia have a family history [2]. Several gene loci, such as *DYT1*, *DYT6*, and *DYT7*, have recently been reported to be associated with cervical dystonia [6].

Cervical dystonia has also been reported to develop secondary to head, neck, and shoulder trauma [7]. The role of the sensory system is important in the pathogenesis of this condition (see section on [symptoms](#)) [8]. Impaired inhibition of sensory Ia afferent fibers, impairment of central sensory pathways, and increased spindle responsiveness secondary to overactive gamma spindle efferent fibers have been proposed as pathogenic mechanisms [9]. Other proposed mechanisms are vestibular impairment, dysfunction of the subcortical-cortical motor network, and dopaminergic dysfunction [9].

The natural course of dystonia has been reported [10], and in 68.1% of patients, dystonia remained focal. Progression of dystonia to sites other than the neck was noted in 31.9% of patients. The only risk factor for progression of dystonia to other body parts was longer duration of the disease. The rate of spontaneous remission was 20.8%. In most of the cases (87%), the remission occurred during the first 5 years after the onset of symptoms. The remission was sustained in 60% of the patients, and in 40% of the patients who had experienced remission, the disorder relapsed (nonsustained remission). The duration of the disease before remission was an important discriminating factor between sustained and nonsustained remission. The patients who experienced nonsustained remission had all done well within the first 2 years of the disorder; whereas in the patients who had sustained remission, the duration of dystonia before remission was more than 2 years.

Symptoms

Symptoms usually begin insidiously with complaints of a pulling or drawing in the neck or an involuntary twisting or jerking of the head. In most patients, the manifesting symptoms are sensory in nature (described variously as pain, pulling, or stiffness) or a degree of head rotation or deviation, with jerking and tremor of the head being distinctly less common complaints [2,4,11]. In 83% of patients, head deviation was constant rather than jerky (i.e., nonspasmodic) and demonstrated some degree of rotation (97%). Only a fraction of patients showed head jerks (35%) and neck spasms (37%), which are the cardinal features of “spasmodic” torticollis [2].

Several provocative and palliative factors are characteristic of idiopathic dystonia. Most notable is the use of a sensory trick or *geste antagoniste*. Gently touching the chin,

back of the head, or top of the head relieves the symptoms. The use of sensory tricks to keep the head in the body midline position was reported by 88.9% of patients in one series [12]. The physiologic mechanism of sensory tricks remains unknown. Other effective maneuvers include leaning against a high-backed chair, placing something in the mouth, and pulling the hair. Early in the illness, these tricks are helpful in most patients, but they tend to lose effectiveness as the disease progresses. Less common palliative factors are relaxation, alcohol, and “morning benefit,” when symptoms are improved for a while after waking. Cervical dystonia is commonly exacerbated by activity (e.g., walking), fatigue, or stress [13].

Pain is a major source of disability in two thirds to three quarters of patients with cervical dystonia [2,3,14,15]. Pain severity was related to the intensity of dystonia and muscle spasms [2] but not to the duration of cervical dystonia and severity of motor dysfunction [14]. Pain was commonly described as tiring, radiating, tugging, aching, and exhausting [14].

Physical Examination

Inspection of the patient's head posture is enough for the diagnosis of cervical dystonia. A wide variety of abnormal head and neck postures can occur (Fig. 4.1). Rotational torticollis is a rotation of the chin around the longitudinal axis toward the shoulder. Laterocollis is a rotation of the head in the coronal plane, moving the ear toward the shoulder. Anterocollis and retrocollis are rotations of the head in the sagittal plane; anterocollis brings the chin toward the chest, and retrocollis elevates the chin and brings the occiput toward the back. By convention, the direction of the rotation is defined by the chin, so right-turning torticollis means that the chin is turning to the right. There may also be sagittal or lateral deviation of the base of the neck from the midline [13]; 66% to 80% of patients present with a combination of these movements [2,4]. The most common component of complex deviations is rotational torticollis, followed by head tilt, retrocollis, and anterocollis. Isolated deviations (e.g., in a single plane) are seen in less than one third of patients. Notably, idiopathic cases of pure anterocollis are extremely uncommon. There is no statistically significant

FIGURE 4.1 Drawing of a patient with left rotational torticollis and laterocollis showing prominent left rotation, left tilt, and shoulder elevation.

preponderance of right or left deviation [2,4,5,16]. The abnormal posture is present for more than 75% of the time in most patients, but findings may change in nature and directional preponderance over time [2].

Many patients have signs of dystonia involving other body segments at the time of presentation. Extracervical dystonia is found in 10% to 20% of patients [2,4]; the jaw (oromandibular), eyelids (blepharospasm), arm or hand (writer's cramp), and trunk (axial) are the most frequently affected parts. A postural or kinetic hand tremor is found on physical examination in up to 25% of patients.

Although the term *spasmodic torticollis* implies head jerking or neck spasms, this feature is absent in 25.33% of patients. The adjectives *spasmodic* and *spastic* are misleading because there is no evidence that cervical dystonia is a spastic disorder or caused by dysfunction of the pyramidal tracts. Furthermore, the movements are not always spasmodic but may be sustained.

Although abnormal head position is enough for the diagnosis, physical examination in patients with cervical dystonia must be focused on detection of “pseudodystonia” secondary to structural abnormalities [17]. Normal findings in a complete neurologic examination are mandated to exclude secondary dystonia. The presence of corticospinal, sensory, cerebellar, oculomotor, or cortical signs with cervical or extracervical dystonia suggests secondary dystonia.

Functional Limitations

Functional limitations due to cervical dystonia are found in almost all patients (99% of 220 patients) [16]. The severity of disability ranges from mild (subjective feeling of discomfort in social conditions without objective consequences on social life) to severe (qualitative and quantitative modification of the occupational level with resulting impairment of social life). One report documented depression in 24% of 67 patients with idiopathic cervical dystonia [18].

At some point during the illness, 75% of patients complain of pain, and patients usually consider the pain a major source of disability [2,4,10,15]. Pain is associated with constant head turning, greater severity of head turning, and presence of spasms [2]. Disability is also caused by task-specific limitations (e.g., inability to drive) and avoidance of social interaction due to abnormal posture. Questioning of patients about disability and clarification of the contributing factors are crucial for the optimal care of patients with idiopathic cervical dystonia [19].

Diagnostic Studies

Screening biochemical studies (blood chemistry screening test, complete blood count, thyroid function) in addition to a ceruloplasmin level should be performed to rule out other medical conditions that might cause dystonic features. Because various central nervous system lesions are known to be associated with cervical dystonia, magnetic resonance imaging of the brain and cervical spine should be considered in all patients with a fixed painful neck posture [20]. If there is scoliosis, it may be evaluated with plain radiographs to document the baseline abnormality. In addition,

Wilson disease should be excluded in all patients younger than 50 years by measurement of serum ceruloplasmin and a slit-lamp examination.

Differential Diagnosis

Atlantoaxial dislocation
Cervical fracture
Degenerative disc
Osteomyelitis
Klippel-Feil syndrome
Congenital torticollis associated with absence or fibrosis of cervical muscles
Postirradiation fibrosis
Acute stiff neck
Pharyngitis
Painful lymphadenopathy, adenitis
Vestibulo-ocular dysfunction (head tilt with fourth nerve paresis or labyrinthine disease)
Posterior fossa tumor
Arnold-Chiari syndrome
Bobbie-head doll syndrome (with third ventricle cyst)
Nystagmus
Sandifer syndrome
Spinal cord tumor or syrinx
Extraocular muscle palsies, strabismus
Head thrusts with oculomotor apraxia
Hemianopia
Spasmus nutans
Focal seizures

Treatment

Initial

The goals of treatment are to palliate, to improve the quality of life, and to prevent secondary complications. Reassurance is most important. Patients should be reassured that cervical dystonia is not dangerous and be reminded that cervical dystonia does not become generalized but may spread locally. However, they should also be told that treatment is symptomatic, not curative. Physicians must understand which aspects of the illness are most limiting because disability in cervical dystonia may be caused by many factors, such as pain, abnormal posture, functional limitation, social embarrassment, and depression. Detection of concomitant depression is crucial because it is a major source of disability, will limit therapeutic benefit, and is itself treatable. Secondary complications, such as radiculopathy, myelopathy, and dysphagia, must be recognized and treated. The evaluation of therapies for cervical dystonia is difficult: the abnormal postures, pain, and disability are not easy to quantitate; there are spontaneous remissions; and most studies are small and not randomized controlled trials [21]. Therefore, no universally accepted treatment protocol exists. However, the treatment of cervical dystonia has been revolutionized by chemodenervation with botulinum toxin. Medications are generally used as adjuncts to botulinum toxin. Adjunctive medications can prevent development of neutralizing antibodies because it is possible to lower dosages and frequency of botulinum toxin injections. Anticholinergics, benzodiazepines, and baclofen are the most widely used.

Other medications, such as dopamine-depleting agents (e.g., tetrabenazine) [22], are available, and many patients will require combination therapy. If therapy with botulinum toxin and oral medications fails, surgery may be required [9].

Rehabilitation

Patients with mild symptoms may be managed with physical measures or pharmacotherapy. Physical measures include the simple *geste antagoniste* (i.e., sensory tricks), biofeedback, mechanical braces, and physiotherapy. Use of the manipulative approach in the treatment of cervical dystonia is not appropriate under the assumption that the condition results from a spinal or orthopedic abnormality. In most patients, it is not possible to physically overcome the brain's disordered central processing commands to displace the head position. Therefore physiotherapists and chiropractors are advised not to use orthopedic techniques or physical force as this may result in further discomfort or injury to the patient. However, it is beneficial to assist patients to use their own resources to improve head control by strengthening and enhanced flexibility.

Physical therapy is recommended as an adjunct to botulinum toxin injection. After treatment with botulinum toxin, there is less opposition from the dystonic musculature. The goal is to facilitate the patient's increased control over head movement and posture once the antagonists are weakened. In a case report, reduction of the effective dose of botulinum toxin was also possible when physiotherapy management was added to a long-term treatment regimen [23].

Procedures

The prognosis of patients with cervical dystonia has been radically changed after the introduction of chemodenervation with botulinum toxin. Compared with all previous therapies, botulinum toxin benefits the highest percentage of patients in the shortest time, has been proved effective in many double-blind placebo-controlled and open trials [24], and has fewer side effects than other pharmacologic therapies [25]. For idiopathic cervical dystonia, serotype A is most widely used. The use of serotypes B and F is under investigation in patients who have become immunologically resistant to serotype A [26].

The identification of the sites of pain and the muscles responsible for the abnormal posture is the most important factor in botulinum toxin administration. The sternocleidomastoid, trapezius, splenius capitis, and levator scapulae are most commonly injected. An electromyographic study of 100 patients found that two or three muscles are most commonly abnormal [27]. In a recent study, ¹⁸F-fluorodeoxyglucose positron emission tomography/computed tomography was suggested to be a useful modality to identify dystonic cervical muscles [28]. The most commonly found abnormal muscles in each head posture are shown in Table 4.1. There is wide variability in the number of muscles injected, the number of injections per muscle, the concentration of botulinum toxin employed, and the use of electromyography-assisted injections, among other technical details. Which technique provides optimal results remains to be determined [29]. The average optimal dose

Table 4.1 Head Postures and the Muscles Most Commonly Responsible for the Posture

Head Posture	Responsible Muscles
Rotational torticollis	Contralateral SCM Ipsilateral SC With or without contralateral SC
Laterocollis	Ipsilateral SCM, SC, TPZ
Retrocollis	Bilateral SC

SCM, sternocleidomastoid; SC, splenius capitis; TPZ, trapezius. Modified from Deuschl G, Heinen F, Kleedorfer B, et al. Clinical and polymyographic investigation of spasmodic torticollis. *J Neurol* 1992;239:9-15.

for patients with cervical dystonia is varied between trials (mean Botox dose: 188 units [50 to 280 units]; mean Dysport dose: 577 units [250–1000 units]) [30]. It is important to customize the dosage and the muscles to suit the needs of the individual patients. The optimal dosing in a particular muscle has been assessed only for the sternocleidomastoid muscle by quantitative electromyography. Doses as small as 20 units of Botox reduced dystonic activity in the sternocleidomastoid muscle, whereas doses larger than 20 units offered minimal additional improvement [31]. Similarly, for Dysport, 100 units was sufficient to reduce the sternocleidomastoid muscle activity [31]; doses larger than 100 units were associated with a greater occurrence of dysphagia [32].

A benefit from botulinum toxin is generally seen within the first week but rarely may be delayed for up to 8 weeks. The benefit lasts an average of 12 weeks, and most physicians suggest that the injections be repeated every 3 to 4 months. The response to toxin is not affected by the pattern of deviation. Continued toxin injections provide progressive improvement of dystonia [29].

Patients with cervical dystonia who never benefit from botulinum toxin injection are considered primary nonresponders. This occurs in approximately 15% to 30% of patients [33]. In addition to the occurrence of primary treatment failure (patients never responding to injection), secondary failure may also occur in 10% to 15% of patients. These patients with initial improvement after treatment fail to respond to subsequent injections. Of the secondary failures, 35.7% were found to have antibodies to botulinum toxin by the mouse neutralization assay [33].

Surgery

Surgical therapy is recommended only for patients whose dystonia is prolonged, unresponsive to adequate trials of medication and botulinum toxin injections, and associated with significant pain or disability. Since the introduction of botulinum toxin, surgery is rarely required. Peripheral denervation procedures designed to denervate dystonic muscles selectively are the most widely practiced surgical procedures. Selective ramisectomy is a procedure that involves the selective section of dorsal rami of the upper cervical spinal nerves [34]. Selective denervation procedures are often combined with selective spinal accessory nerve section, anterior rhizotomy, or myotomy. Deep brain stimulation is becoming the standard of care for medically intractable, disabling dystonias. Advantages of deep brain stimulation include reversibility, adjustability, and

continued access to the therapeutic target. Initial reports describing the use of deep brain stimulation in generalized dystonia have been encouraging, and experience in the use of deep brain stimulation to treat various forms of dystonia is continually growing [35].

Potential Disease Complications

Patients may develop cervical spondylosis with resulting radiculopathy or myelopathy [36]. Extracervical spread of dystonia is a progression of dystonia to a segmental pattern of dystonia. In one third of 72 patients who first had isolated cervical dystonia, the dystonia typically spread to the face, jaw, arms, or trunk [10].

Potential Treatment Complications

Side effects of botulinum toxin injections have been reported in 20% to 30% of patients per treatment cycle and approximately 50% of patients at some time during therapy. Dysphagia, neck weakness, and local pain at the injection site are the most commonly reported side effects, but dizziness, dry mouth, influenza-like syndrome, lethargy, dysphonia, and generalized weakness have been reported. The frequency of side effects varies widely, apparently on the basis of the dosage used [26].

Failure to spare ventral roots in selective ramisectomy injures the cervical and brachial plexuses and leads to the complications of diaphragmatic paralysis and dysphagia. Other sequelae of the selective denervation procedure include sensory loss in the distribution of the greater occipital nerve, paresthesias, and occasional sudden tic-like pain.

CHAPTER 5

Cervical Radiculopathy

Ali Mostoufi, MD, FAAPMR, FAAPM

Synonyms

Radiculopathy, cervical region
Brachial neuritis or radiculitis

ICD-9 Code

723.4 Cervical radiculitis

ICD-10 Codes

M54.12 Cervical radiculitis

M54.13 Cervicothoracic radiculitis

Definition

Cervical radiculopathy is dysfunction of a cervical nerve root resulting in pain in the neck and arm with associated sensory, motor, and reflex abnormalities. Involvement of the ventral root of the spinal nerve results in motor weakness, and involvement of the dorsal root of the spinal nerve results in sensory deficits. Involvement of either root may result in reflex abnormality because the reflex arc comprises both (pertinent to C5, C6, and C7). In most cases, both the ventral and dorsal roots are affected, resulting in motor and sensory cervical radiculopathy.

Cervical radicular pain refers to neck pain radiating to the arm in a specific nerve root pattern, but it is not necessarily associated with loss of sensation, motor deficit, or reflex abnormality. A patient could experience radicular neck pain without abnormal physical examination findings that are characteristic of radiculopathy.

Cervical spine anatomy is complex (Fig. 5.1). There are seven cervical vertebrae (C1-C7). The C1 vertebra is ring shaped, and its lateral masses articulate with the occipital condyle of the skull. The vertebral body of C2 is marked by the cephalad extension of the dens, which is secured in place by the transverse ligament. There

are six intervertebral discs (C2-C7) located anteriorly in between vertebral bodies of adjacent vertebrae. C2-C7 vertebrae articulate posterolaterally through facet joints, which are situated in the coronal plane with inferior angulations. C3-C7 vertebrae also have a unique articulation through the uncovertebral joint. There are eight pairs of cervical nerve roots. The names of the cervical nerves correspond to the vertebral body below the nerve, except C8. The C8 roots exit at the C7-T1 intervertebral foramen. The foramina are largest in the upper cervical spine and gradually narrow distally, with the C7-T1 foramen being the narrowest [1]. Cervical nerve roots exit through the inferior portion of the cervical intervertebral foramina [1]. The C1-C3 spinal nerves have dorsal innervations including suboccipital (C1), greater occipital (C2), and third occipital nerves (C3) [2]. The C1-C4 ventral primary rami form the cervical plexus, and the C5-C8 ventral primary rami contribute to the brachial plexus innervating the arm [3]. Each cervical intervertebral foramen is bordered posterolaterally by the zygapophyseal joint (facets), anteromedially by the uncovertebral joint, and inferiorly and superiorly by the pedicles of the adjacent vertebrae. Intervertebral discs are located anteriorly, and they separate vertebral bodies to lend height to the intervertebral foramina.

The most common radiculopathy is C7, followed by C6, C8, and C5 in descending order of incidence [4]. The most common reasons for cervical radiculopathy are posterolateral herniated disc (Fig. 5.2); narrowing of the neuroforamina due to facet spondylosis; hypertrophied uncinate process with neuroforaminal encroachment; and spondylolisthesis, with or without instability, narrowing adjacent neuroforamina. Less common causes include facet synovial cyst with encroachment of nerve root, extradural mass, spinal tumors, and abscess. Other medical conditions that resemble cervical radicular symptoms should be carefully ruled out as part of medical evaluation of neck and arm pain (Table 5.1). These include musculoskeletal, neurologic, and rheumatologic disorders.

Symptoms

The most common symptom of cervical radiculopathy is neck pain with associated unilateral arm pain in a specific

FIGURE 5.1 A, Comparison of points at which nerve roots emerge from cervical and lumbar spine. B, Cross-sectional view of cervical spine at level of disc (D). Uncinate process (U) forms ventral wall of foramen. Root (N) exits dorsal to vertebral artery (A). (From Canale ST, Beaty JH, eds. *Campbell's Operative Orthopaedics*, 12th ed. St. Louis, Elsevier/Mosby, 2013.)

FIGURE 5.2 Sagittal (A) and axial (B) magnetic resonance images of left paracentral C6 herniated disc. Posterolateral herniated disc is the most common cause of cervical radicular pain. Traversing nerve root can be abutted, displaced, or compressed by the herniated segment, resulting in radicular pain and radiculopathy.

SLAP, Superior labral tear from anterior to posterior.

nerve root pattern. Sensory complaints of numbness, tingling, burning, or electrical sensation follow a dermatomal pattern, and weakness follows the same anatomic-level myotomal pattern. Of the subjective complaints, the distribution of hand paresthesias appears to have the greatest localizing value [5]. Literature supports that suprascapular (C5-C6), interscapular (C7), and scapular (C8) pain suggests radiculopathy [6]. Symptoms can be aggravated by motion of the head toward the painful side, free hanging of the arm, lifting of heavier items, coughing, sneezing, and Valsalva maneuver. Pulling, pushing, and lifting of items are often not tolerated in the acute phase. Pain may improve when the head is tilted away from the painful side or if the affected arm is abducted over the head. Clumsiness, fine motor deficits, and mild grip weakness may precede gross weakness. Clinicians should routinely inquire about symptoms of myelopathy. Myelopathy symptoms are bilateral hand numbness or paresthesias, altered dexterity, poor balance, falls, and bowel or bladder dysfunction. These symptoms are not features of a discrete radiculopathy and should alert the clinician to rule out spinal cord compression.

Physical Examination

A complete musculoskeletal and neurologic examination is indicated in the evaluation of cervical radiculopathy. Special attention is needed to differentiate between objective findings compatible with radiculopathy and myelopathy signs. Physical examination needs to be expanded if other system involvement is suspected.

Visual Observation

Simple observation is a first step to proper diagnosis and treatment. A clinician's eyes should be trained to notice

poor posture, body mechanics, spinal deformity, muscle atrophy, asymmetric gait, use of assistive devices, skin abnormalities, and nonverbal behaviors.

Gait Evaluation

Examination of gait is an important step in differentiating radicular neck pain from myelopathy. Gait should be normal in cervical radiculopathy and could be abnormal in cervical myelopathic patients.

Palpation

In patients with radiculopathy, ipsilateral tenderness and muscle spasm are common. The clinician should examine muscles for taut bands or tender points.

Range of Motion

Range of motion (ROM) of the cervical spine in all planes should be examined and deficits should be documented. Clinicians should carefully reevaluate ROM of the cervical spine to monitor progress in treatment. The normal cervical ROM is as follows: extension, 55 degrees; flexion, 45 degrees; lateral bending, 40 degrees; rotation, 75 degrees [7]. Among activities of daily living, backing up a car requires the most available range. Personal hygiene, such as hand washing, shaving, and applying makeup, necessitates a significantly greater cervical ROM relative to mobility activities of daily living, including walking and negotiating stairs [7].

Sensory Testing

Radiculopathy results in dermatomal sensory abnormality in the neck, shoulder girdle, and ipsilateral arm. On the basis of the specific dermatomal deficits, a clinician can localize the anatomic level of nerve root impingement. Light touch, pinprick, two-point discrimination, proprioception, and vibration sense should be tested in both the symptomatic and symptom-free arm. There is a degree of overlap between dermatomal innervations of the arm. To date, the International Standards for Neurological Classification of Spinal Cord Injury is the most standardized sensory testing guideline [8]. For consistent examination, the use of these guidelines is recommended to examine sensory function in the upper limb (Fig. 5.3).

Deep Tendon Reflexes

The most frequently tested reflexes in the upper limb are the biceps brachii (innervation C5/6, C5 primary), the brachioradialis (C5/6, C6 primary), and the triceps (C7 primary). Reflexes are tested bilaterally and compared. Hyporeflexia (diminished) or areflexia (complete absence) indicates involvement of the lower motor neuron, including the specific nerve root tested. Hyperreflexia (increased or brisk reflex) is an indication of central nervous system involvement. The response levels of deep tendon reflexes are graded 0 to 4+, with 2+ being normal (Table 5.2 and Fig. 5.4).

FIGURE 5.3 Key sensory points examination of the upper extremity.

Table 5.2 Muscle Group and Sensory Point Testing in Cervical Radiculopathy [8]: Upper Extremity Key Reflexes

Root	Reflex	Key Muscle Group (neck and arm)	Key Sensation Point
C2	Normal reflexes	Neck flexion	1 cm lateral to occipital protuberance
C3	Normal reflexes	Neck extension and lateral flexion	Supraclavicular fossa, mid-clavicle line
C4	Normal reflexes	Shoulder elevation	Skin over acromioclavicular joint
C5	Diminished biceps deep tendon reflex	Elbow flexor	Radial side of the antecubital fossa
C6	Diminished brachioradialis deep tendon reflex	Wrist extension	Dorsal surface, proximal phalanx of the thumb
C7	Diminished triceps deep tendon reflex	Elbow extension	Dorsal surface, proximal phalanx of the third digit
C8	Normal reflexes	Long finger flexors	Dorsal surface, proximal phalanx of the fifth digit

FIGURE 5.4 The Adson maneuver (A) tests for radial pulse obliteration and is a screening tool for thoracic outlet syndrome. The brachioradialis reflex is often diminished in C5-C6 radiculopathy (B).

Motor Testing

Subjective weakness in the upper limb is a common complaint in patients with radiculopathy. Patterns of weakness can help localize a lesion to a particular spinal cord level, nerve root, peripheral nerve, or muscle. Comparison of the strength of each muscle group with its contralateral counterpart allows the detection of any asymmetries. The degree of pain and the patient's effort can be limiting factors in the examination of muscle strength. Relevant to cervical radiculopathy, strength testing is often focused on muscles innervated by the C4-C8 nerve roots. The International Standards for Neurological Classification of Spinal Cord Injury has standardized and recommends testing of five key muscles in the upper limb: C5 elbow flexors, C6 wrist

extensors, C7 elbow extensor, C8 long finger flexors, and T1 small finger abductor [8] (Table 5.3). Muscle strength is rated on a scale of 0/5 to 5/5. When weakness is detected in one of the key muscle groups, the clinician has to reexamine individual muscles in the arm to further localize the lesion (brachial plexus roots vs trunks vs divisions vs cord).

Joint Examination

Cervical facets can be examined by ROM testing and also by localized external pressure on them. These maneuvers may reproduce neck pain or head pain concordant with the patient's nonradicular complaint. Referred pain from facets

Table 5.3 Sample of Neck and Arm Muscles or Muscle Groups Innervated by Cervical Roots [3,33]

Root	Muscle or Muscle Group
C2	Sternocleidomastoid, rectus capitis, longus colli
C3	Trapezius, splenius capitis
C4	Trapezius, levator scapulae
C5	Elbow flexors, deltoid, biceps, supraspinatus, infraspinatus
C6	Wrist extensors, biceps, brachioradialis, supinator
C7	Elbow extensors, wrist flexors, triceps
C8	Flexor digitorum superficialis, thumb extensor and adductors, wrist ulnar deviators

to the shoulder girdle or scapular region may be confused with radicular pain of similar distribution. Careful examination of the shoulder as well as of the elbow and wrist is also important in differentiating radicular neck pain from other musculoskeletal causes of arm pain.

Special Maneuvers

The Spurling maneuver is a classic test used to identify nerve root irritation (Fig. 5.5). This test is a combination of ipsilateral tilt and forward flexion of the neck while the examiner exerts axial load. The modified Spurling test is a combination of ipsilateral rotation, extension, and axial compression of the head. Reproduction of the patient's radicular symptoms (distal to the shoulder) in either maneuver is considered a positive test result. Several studies have shown that the Spurling test has a low sensitivity (30%-40%), high specificity (80%-90%), and fair to good interexaminer reliability [9,10]. The Spurling test should be avoided if fracture or instability is suspected.

Clinicians should be familiar with the Adson and Roos tests in examining patients with neck and arm pain (see

Fig. 5.4). Pain, weakness, and neurovascular deficits are associated with thoracic outlet syndrome, part of the differential diagnosis of cervical radiculopathy.

Lhermitte sign is a sudden painless electric shock-like sensation originating in the neck and spreading down the spine into the limbs when the patient's neck is flexed. This test was described in a 1924 publication by Lhermitte [11]. Although nonspecific, it is most commonly seen in multiple sclerosis as well as in myelopathy due cervical spondylosis, spinal cord tumors, epidural bleed, and postirradiation therapy.

The neck distraction sign and shoulder abduction test can also determine nerve root irritation [10]. Babinski response, Hoffmann sign, and clonus are also part of the examination of the patient with cervical radiculopathy and may suggest involvement of the central nervous system.

Functional Limitations

Pain commonly interferes with sleep, work, or social activities. With restriction in ROM, driving, overhead activity, and reading may be difficult. Desktop computer work and use of tablet computer and smartphone may result in increased pain. Loss of sensation in the fingers may negatively affect individuals who rely on tactile function for their work. Grip weakness may lead to dropping of items, and proximal muscle weakness will affect the ability to carry items or to pull and push objects. Patients with failed medical and surgical treatments often experience permanent impairment resulting in chronic disabilities.

Diagnostic Studies

Radiography

Radiography is seen as the initial imaging modality to evaluate anatomic changes in the bone structure of the cervical

FIGURE 5.5 The Spurling maneuver (A) and the modified Spurling maneuver (B) test for cervical root irritation. A positive test result is the reproduction of pain and paresthesia in the arm.

spine. It is sensitive to evaluate fractures, misalignment, spondylolisthesis, facet arthrosis, and disc space narrowing. It can identify instability of the cervical spine by means of dynamic and open mouth views. Although it is often used in urgent care settings for patients with radicular pain, apart from showing the bone narrowing of the neuroforamina and disc space narrowing, it is of little value.

Computed Tomography

Computed tomography (CT) provides exquisite depiction of bone detail of the cervical spine. It is particularly useful in and is considered a primary imaging evaluation for acute spine trauma in adults [12]. It is an excellent modality in multitrauma workup of fractures (C1, C2, and distal cervical segments) and possible bleeding in or around the spinal canal. Because it is a cross-sectional imaging technique, it is able to identify bone narrowing of the central canal and neuroforamina and thickening of the ligamentum flavum. CT is the modality of choice in patients with implanted pacemakers and other devices that do not allow the use of magnetic resonance imaging (MRI). CT with axial and coronal reconstruction is used to identify proper fusion of the adjacent vertebrae after spinal fusion surgery. CT myelography has some indications in complex surgical revisions or postsurgical cases with persistent arm symptoms. CT is used after discography is performed to better visualize internal disc derangements, including radial tears. CT is also used in the workup of possible infection, as in spinal abscess.

Magnetic Resonance Imaging

Compared with CT, MRI is a clinically superior diagnostic test in the evaluation of patients with suspected disc herniation. It should be the diagnostic study of choice when it is available.

MRI is the “gold standard” imaging study for patients with radicular symptoms. It can clearly identify soft tissue abnormalities, including the cord, muscles, and ligaments. With axial images, clinicians can gauge the caliber of the spinal canal and the neuroforamina. With T1- and T2-weighted images, signal abnormality within the spinal cord substance (myelomalacia) and bone marrow can also be evaluated. Acuity of cervical spine fractures as well as primary or metastatic tumors of the spinal column can be assessed by this imaging modality. MRI before and after the administration of a contrast agent is necessary to define certain conditions like cancerous lesions and postsurgical scarring. In workup of a possible infection, MRI can help identify soft tissue signal abnormality, local fluid collection, osteomyelitis, discitis, and abscess formation. Interpretation of the MRI study is difficult after spinal instrumentation because of metallic artifact. In such cases, CT becomes the imaging of choice.

Bone Scan

The utility of the bone scan in spine care is limited to spondylolysis, infection, and metastatic or primary spinal tumors.

Electrodiagnosis

Nerve conduction studies and electromyography are considered an extension of the physical examination. In patients

with clear cervical radicular symptoms, supportive MRI, and concordant examination findings, there is no indication for electrodiagnosis. Nerve conduction studies and electromyography can be useful if there is clinical suspicion of peripheral neuropathy or peripheral entrapment that is manifested with symptoms similar to cervical radicular pain. Electromyography can be an additional tool in those cases in which symptoms, physical examination findings, and imaging results are not concordant [13].

Myelography

Before the advent of MRI, myelography was a useful test to examine the caliber of the central canal and intervertebral foramen and possible compression on the nerve root. Its use is currently limited to complex postsurgical cases, surgical revisions, and evaluation of spinal tumors.

Diagnostic Spinal Injections

Fluoroscopically guided contrast-enhanced procedures can deliver medications to a desired target. In complex cases in which multilevel degenerative changes are seen and there is a question of which segment is contributing to the arm pain, spine surgeons may ask for a diagnostic selective nerve root injection. The degree of pain relief within the half-life of the injected anesthetic can provide valuable preoperative information to the surgeon and increase the likelihood of successful surgical treatment. The evidence for selective nerve root blocks in the preoperative evaluation of patients with normal or inconclusive imaging studies is moderate [14].

Provocative discography has been used to diagnose discogenic axial pain. For cervical discogenic pain, discography has a level II-2 support (U.S. Preventive Services Task Force classification, evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group) [15]. Complications associated with cervical discography because of the surrounding anatomy include injury to the trachea, esophagus, carotid artery, and jugular veins; nerve root or spinal cord injury; and pneumothorax [3]. The potential complication of discitis is also of concern in considering diagnostic discography [3]. Because there are no well-designed studies to support cervical discography as a diagnostic tool for discogenic neck pain, such a procedure should be considered with utmost caution.

Treatment

Initial

With conservative care, 70% to 80% of patients with cervical radicular symptoms improve [16]. Pain reduction and patient education are important initial goals. For the acute phase, one can consider the use of ice as well as passive treatment consisting of semihard cervical collar immobilization and rest from activities that aggravate the condition. Nonsteroidal anti-inflammatory drugs, muscle relaxants, and, at times, short tapering doses of an oral steroid can be the initial recommended medication treatment for most patients. Stronger pain medications are indicated on the basis of the severity of the pain. In some

cases, adjunct medication like anticonvulsants, tricyclic antidepressants, or selective norepinephrine reuptake inhibitors may be used.

Timely involvement of a physical therapist appears beneficial. Manual therapy techniques in conjunction with therapeutic exercise are effective in increasing function, improving active ROM, and decreasing pain and disability [17]. The scientific literature supports the use of cervical traction for management of pain as well as improvement in function and strength in patients with cervical radiculopathy [18,19]. Acupuncture and massage can help reduce muscle tension and pain. There is moderate quality evidence that spinal manipulation is effective for the treatment of acute radiculopathy [20]. It is the responsibility of health care providers to educate patients about their condition and to suggest ways to prevent worsening and recurrence of the symptoms by activity modification, appropriate body mechanics (neutral spine), proper lifting techniques, suitable pillow and mattress use, and appropriate exercises.

Rehabilitation

In the management of cervical radicular pain, early involvement of physical and occupational therapy services is encouraged. The rehabilitation program should focus on reduction of muscle spasm, improvement in ROM, and improvement of muscle strength. Cervical stabilization, stretching (passive and active), static strengthening, and progressive resistive exercises are incorporated in the rehabilitation phase and should be transitioned to a home exercise program [21]. Thermal modalities, manual traction, and transcutaneous electrical nerve stimulation are often used by physiotherapists for temporary pain reduction during this phase. Interventional procedures and medications can reduce pain and increase the patient's compliance with rehabilitation. Within the framework of rehabilitation, the patient is educated on body mechanics, proper desk ergonomics, and use of adaptive equipment (e.g., book stand, hands-free phone or headset, and document holder).

Procedures

Interlaminar Epidural Steroid Injections

Cervical epidural steroid injection is indicated in persistent painful cervical radiculopathy despite appropriate initial medical and rehabilitation treatments. In the hands of trained physicians, when it is done with image guidance, it is a safe and effective treatment. On the basis of a systematic review of the literature, the evidence for treatment of cervical radicular pain with interlaminar epidural steroid injection is good [22,23]. There is no indication for performing these injections in a series.

Selective Nerve Root Block

Cervical selective nerve root block is a diagnostic procedure. If a patient has substantial decrease in pain with image-guided contrast-enhanced injection of anesthetics at a specific nerve root, the clinician can consider that specific nerve root to be the main cause of arm pain. Surgeons use such information to plan for surgical management of radiculopathy [24]. Selectivity of such injection is lost if there is epidural

spread of the injectate. Some interventional practitioners use particulate steroids when performing a selective nerve root block to treat cervical radicular pain. Given the probability of vascular injection of steroid in this technique and potential catastrophic complications (brain and spinal cord infarction), clinicians should carefully gauge the benefit versus risk when choosing transforaminal epidural injection as a treatment for their patients [25,26]. Use of digital subtraction imaging and nonparticulate steroids is encouraged. Like all interventions, this procedure should be done by fellowship-trained physicians.

Surgery

Progressive neurologic deficit, development of myelopathy, and failed conservative care are indications for spinal surgery. Surgical intervention has been shown to provide faster improvement in pain, sensory disturbance, and muscle strength at 3 months postoperatively than conservative treatment [27]. It is not clear from the evidence that long-term outcomes are improved with the surgical treatment of cervical radiculopathy compared with nonsurgical measures [28]. It is not evident that one open surgical technique is clearly superior to others for radiculopathy [28]. Decision-making for discectomy alone or discectomy and fusion with or without foraminotomy is affected by the degree of anatomic change, previous spine surgery, existence of instability, coexisting spondylolisthesis, amount of neck pain in addition to arm pain, and preference of the surgeon. Fusion can be achieved anteriorly (anterior cervical discectomy and fusion) (Fig. 5.6) or posteriorly (posterior cervical fusion). Disc arthroplasty is a newer technique for management of cervical disc diseases; it maintains segmental height and motion. These devices have been shown to have efficacy similar to that of anterior cervical discectomy and fusion [29].

Potential Disease Complications

Possible complications of cervical radiculopathy are persistent or progressive neurologic weakness, residual neck or radicular pain, chronic pain syndrome, disability, and myelopathy (rare, usually associated with spondylosis or large central disc herniation).

Potential Treatment Complications

Medications used to treat cervical radiculopathy can result in class-specific side effects. Nonsteroidal anti-inflammatory drugs commonly have gastrointestinal and renal side effects. Muscle relaxants, selective norepinephrine reuptake inhibitors, and tricyclics can cause central nervous system suppression. Steroids result in endocrine side effects, including hyperglycemia, hypothalamus-pituitary-adrenal axis impact, and amenorrhea. Narcotics can cause nausea, constipation, respiratory suppression, mental status changes, and suppression of endogenous opioids; dependence, tolerance, and abuse may also result.

Manipulation may exacerbate symptoms. Although rare, progressive weakness, carotid dissection, and recurrence of herniation have been reported in connection with cervical spine manipulation [30].

FIGURE 5.6 A, C3-C6 anterior cervical discectomy and fusion hardware on standard lateral fluoroscopic view (needles placed for treatment of facetogenic headache). B, Transforaminal needle placement in cervical spine and injection of contrast material confirm flow along the descending C6 nerve root sleeve and ipsilateral epidural gutter.

Interventional injections may result in transient increased pain, facial flushing, hyperglycemia, allergic reaction to injectate, and vasovagal reaction. Vasovagal reaction is the most common minor complication [31]. Infection, nerve injury, vascular insult, epidural hematoma, and spinal cord injury are rare but more serious complications that may occur after such invasive procedures. Experienced interventionalists can limit such complications by exercising sterile technique, performing image-guided contrast-enhanced procedures, and withholding anticoagulants and antiplatelets before elective procedures. Cervical transforaminal steroid injection carries the additional risk of vascular injection of steroid, which may lead to brain and spinal cord infarction due to the embolic phenomenon of particulate steroids [26]. Use of digital subtraction imaging and nonparticulate steroids may reduce such risk [32]. Interventional spine procedures should be performed only by fellowship-trained physicians specifically trained in such procedures.

Acknowledgment

The author would like to acknowledge Dr. Asif Jillani for his assistance with this chapter.

Definition

Cervical sprain or strain typically refers to acute pain arising from injured soft tissues of the neck, including muscles, tendons, and ligaments. The most common event leading to such injuries is motor vehicle collision. The mechanism of injury is complex. During a rear-end motor vehicle collision, the initial head and neck acceleration

lags behind vehicular acceleration. Eventually, head and neck acceleration reaches up to 2½ times the maximum car acceleration, which subsequently results in dramatic deceleration at end range of motion of the neck [1,2]. Whereas such injury can also result in fracture, disc, or neurologic injury, cervical strain or sprain, by definition, excludes these entities.

Although these other entities need to be excluded from the differential diagnosis, recent evidence implicates the zygapophyseal joints as a source of neck pain after whiplash injury. Specifically, in a randomized controlled trial in which the medial branches of the cervical dorsal rami were blocked with local anesthetic or treated with saline, it was shown that 60% of patients with whiplash injury had complete neck pain relief after injection of local anesthetic compared with no relief by injection of placebo [3].

Many factors have been associated with worse outcome in acceleration-deceleration injuries involving motor vehicles. Older women tend to have a worse prognosis than that of younger women and men in general. In addition, poor education and a history of prior neck pain are prognostic factors for worse pain in women. Low family income, history of prior neck pain, and lack of awareness of head position in the crash are associated with a poor prognosis in men [4]. Additional crash-related factors associated with a worse outcome include occupancy in a truck, being a passenger, colliding with a moving object, and getting hit head-on or perpendicularly [5]. A high intensity of neck pain, a decreased onset of latency of the initial pain, and radicular symptoms are also prognostic of worse outcomes [6]. Because many of these injuries result in initiation of litigation by patients, this too is a poor prognostic indicator.

Other causes include sleeping in awkward positions, lifting or pulling heavy objects, and repetitive motions involving the head and neck.

Estimates exist that 1 million whiplash injuries each year are due to motor vehicle collisions. The annual incidence varies worldwide, but in North America and western Europe, the incidence is likely to be at least 300 per 100,000 inhabitants [6].

Symptoms

The most common presentation of patients with cervical strain or sprain is nonradiating neck pain (Fig. 6.1). Patients will also complain of neck stiffness, fatigue, and worsening of symptoms with cervical range of motion. The pain often extends into the trapezius region or interscapular region. Headache, probably the most common associated symptom, originates in the occiput region and radiates frontally. Increased irritability and sleep disturbances are common. Paresthesias, radiating arm pain, dysphagia, visual symptoms, auditory symptoms, and dizziness may be reported [7,8]. Whereas an isolated cervical sprain or strain injury should be without these symptoms, there is the possibility of concomitant neurologic or bone injury. If these symptoms are present, alternative diagnoses should be suspected. Myelopathic symptoms, such as bowel and bladder dysfunction, which suggest a different diagnosis that is more serious, must be investigated.

Physical Examination

The primary finding in a cervical sprain or strain injury is decreased or painful cervical range of motion. This may be accompanied by tenderness of the cervical paraspinal, trapezius, occiput, or anterior cervical (i.e., sternocleidomastoid) muscles (Fig. 6.2).

A thorough neurologic examination should be performed to rule out myelopathic or radicular processes. In an isolated cervical sprain injury, the neurologic examination findings should be normal.

The result of the neurocompression test, in which the patient is asked to rotate and extend the head, thereby reducing the neuroforaminal space, should be negative with cases of cervical sprain or strain.

FIGURE 6.1 Typical pain distribution for a patient with an acute cervical sprain or strain injury.

FIGURE 6.2 Muscles commonly involved in a cervical sprain or strain injury.

Functional Limitations

Restricted range of motion of the cervical spine may contribute to difficulty with daily activities, such as driving. Patients often complain of neck fatigue, heaviness, and pain with static cervical positions, such as reading and working at the computer. Sleep may be affected as well.

Diagnostic Studies

It is generally accepted that radiographs to exclude fracture should be obtained in patients involved in a traumatic event and who have altered consciousness, are intoxicated, or exhibit cervical tenderness and focal neurologic signs with decreased range of motion on physical examination [9]. Although the clinician may commonly see straightening of the cervical lordosis on the lateral cervical radiograph, this is thought to be related to spasm of the paracervical musculature and bears no other significance (Fig. 6.3).

Studies such as magnetic resonance imaging scans, computed tomographic scans, and electrodiagnostics are typically used to rule out alternative or coexisting entities.

FIGURE 6.3 Cervical spine radiograph showing straightening of the spine and loss of the normal cervical lordosis.

All of these studies will have normal findings in cases of cervical sprain or strain.

Differential Diagnosis

- Occult cervical fracture or dislocation
- Cervical discogenic pain
- Cervical herniated disc, radiculopathy
- Cervical facet syndrome
- Cervical spine tumor
- Cervical spine infection

Treatment

Initial

Initial interventions used in patients with cervical sprain or strain have not been fully scientifically tested. Education of the patient is essential to minimize iatrogenic disability and cost of health care resources [10], and it is critical for a realistic expectation of resolution of symptoms. In most cases, symptoms will resolve within 4 to 6 weeks. In some cases, however, resolution of symptoms may be delayed up to 6 months.

It is reasonable to recommend relative rest within the first 24 hours of injury. The detriments of prolonged bed rest and the use of cervical collars have been clearly described, and these “treatments” may, in fact, promote disability [11]. The short-term use of nonsteroidal anti-inflammatory drugs, muscle relaxants, and analgesic medications on a judicious basis is accepted to promote early return to activity [12]. Muscle relaxants or low-dose tricyclic antidepressants (nortriptyline or amitriptyline, beginning with 10 to 25 mg at bedtime) are also used to help restore sleep in the patient for whom this is an issue. However, in the acute period, the addition of cyclobenzaprine to ibuprofen did not provide any added benefit in terms of improving pain scores [13].

High-dose intravenous methylprednisolone within 8 hours of the whiplash injury has been studied and was shown to be associated with decreased pain at 1 week after injury and fewer total sick days taken at 6 months. However, larger trials are needed to further evaluate the cost-benefit ratio for this treatment [14].

Rehabilitation

No rehabilitation approach has been proved unequivocally effective, although early mobilization and return to function is the key to successful rehabilitation. An early course of mobilization combined with home exercise in the acute phase of recovery is effective in minimizing disability. Cervical manipulation, massage, and mobilization on a limited basis are geared toward correction of segmental restrictions and restoration of normal range of motion. Such approaches have been shown to be more effective than passive modalities with regard to range of motion and reduction of pain [15]. Therapeutic modalities such as ultrasound and electrical stimulation can be tried for pain control but have no proven efficacy for long-term recovery. In addition, cervical traction done either manually (by a physical therapist) or with a mechanical unit (prescribed for home use) may be tried if there are no contraindications (i.e., fracture). Educational

videos that make recommendations about posture, return to activity, exercise, and pain relief methods may help reduce rates of persistent symptoms at 6 months after injury [16].

Strengthening and stretching exercises for muscles with a tendency for tightness should be used in conjunction with the aforementioned techniques. Muscle imbalances must be addressed, and weak muscle groups such as the scapular stabilizers (middle-lower trapezius, serratus anterior, and levator scapulae) should be strengthened. This is typically done after muscles with a tendency for tightness (upper trapezius, sternocleidomastoid, scalenes, latissimus dorsi, and pectoralis major and minor) are stretched [17]. Cumulative data suggest that such an approach to cervical sprain injuries produces both long- and short-term benefits [9]. The overall treatment goal is to achieve an independent, customized home exercise program so that the patient can become active in his or her treatment [17]. An exercise protocol targeting shoulder and neck muscle strength and endurance was effective in decreasing chronic neck pain and disability in 180 female police officers [18].

Evaluation of the home or work environment by an occupational therapist can also be of benefit. Specifically, ergonomic alterations, such as the use of a telephone headset and document holders, may aid in recovery.

Procedures

Trigger point injections are a reasonable adjunct to decrease pain so that patients may participate in physical therapy. A meta-analysis in 2010 stated that lidocaine injections into myofascial trigger points appear to be effective [19]. The upper trapezius, scalenes, and semispinalis capitis are the most common muscles to develop trigger points after acceleration-deceleration injuries. Other trigger points tend to arise in the splenius capitis, longus capitis, and longus colli after such injuries [20].

Botulinum toxin injections were initially thought to be effective for chronic cervical pain causing headaches [21]; however, there is more recent evidence that botulinum toxin A is not superior to saline injection for chronic mechanical neck pain [19].

Facet injections, epidural injections, and cervical traction may be instituted for conditions such as cervical radiculopathy and facet syndrome.

Surgery

Surgery is not indicated.

Potential Disease Complications

Similar to other grade I soft tissue strains, this injury will heal within 6 weeks. As such, there are no significant complications because this is not a permanent injury. There is research to suggest that the initial level of pain and degree of loss of cervical spine range of motion directly correlate with a poorer prognosis [22]. In addition, older age, lower educational achievement, part-time employment, preexisting neck or low back pain, and previous whiplash injury are associated with a significantly worse outcome. Of note, continuing litigation is associated with more severe pain [23].

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Muscle relaxants and low-dose tricyclic antidepressants can cause sedation. Overly aggressive manipulation or manipulation done when there is a concomitant unidentified injury (i.e., fracture) may result in serious injury. Injections are rarely associated with infection and allergic reactions to the medications used.

Interestingly, there is a correlation between the patient's perception of the severity of the initial injury and the expectations for recovery [24]. It is for that reason that patient education is a significant focus in the treatment of cervical strain, and therefore lack of education may have negative effects. Thus far, a meta-analysis in 2012 has not shown scientifically that education is truly beneficial [25].

myelopathy or radiculopathy
M48.02 Spinal stenosis in cervical region
M48.03 Spinal stenosis in cervicothoracic
region

Definition

Cervical spinal stenosis refers to pathologic narrowing of the spinal canal that can be either congenital or acquired. The congenital type is commonly due to short pedicles that produce an abnormally shallow central spinal canal [1]. Less frequently, congenital stenosis may be associated with developmental disorders, such as achondroplasia, Klippel-Feil syndrome, Morquio syndrome, and trisomy 21 (i.e., Down syndrome) [2,3]. The main contributing factors in development of the acquired type are the degenerative, hypertrophic, age-related changes that affect the intervertebral discs, facet joints, and uncovertebral joints as well as the ligamentum flavum (Fig. 7.1). On radiologic imaging, these degenerative changes are present in 25% to 50% of the population by the age of 50 years and in 75% to 85% by 65 years [4–6]. Some of the other factors that may contribute to pathologic narrowing of the spinal canal are degenerative spondylolisthesis,

ossification of the posterior longitudinal ligament, and atlantoaxial subluxation as seen in rheumatoid arthritis; rarely, it may be secondary to such extradural pathologic processes as metastatic disease, abscess formation, and trauma [7]. Aside from age, other demographic factors do not contribute significantly to the development of cervical stenosis [8]. Whereas ossification of the posterior longitudinal ligament was once considered specific to the Japanese, it has since been well documented in Western and other Asian populations [9].

Symptomatic spinal cord compression, or cervical myelopathy, commonly occurs at the cervical levels C5–C7, given the relatively increased mobility of these segments and the subsequent development of degenerative “wear and tear.” Concomitant compression of the exiting cervical nerve roots is also typically observed in cervical spondylotic disease. Symptom production can occur by constant, mechanical compression of the neural elements or be of an intermittent, dynamic nature as seen with extremes of cervical flexion and extension. Chronic compression can lead to local cord ischemia with subsequent development of cervical myelopathy [10].

Symptoms

Symptomatic presentation of cervical spinal stenosis can differ from patient to patient, depending on the pathologic process, the anatomic structures, and the cervical levels involved. Intervertebral disc degeneration and zygapophyseal joint arthritis commonly are manifested with axial neck pain. Patients with cervical foraminal stenosis may complain of radicular arm pain as well as of paresthesias, dysesthesias, numbness, and weakness of the upper extremity. On the other hand, patients with cervical central canal stenosis can present with myelopathic symptoms of the upper and lower extremities, neurogenic bladder or bowel, sexual dysfunction, and unsteady and stiff-legged gait as well as weakness, paresthesias, or numbness of the lower extremities. Lower extremity pain is not known to be a clinical symptom unless concomitant lumbar spinal disease is present.

Physical Examination

Physical examination findings of the patient with cervical stenosis should be consistent with upper or lower motor

FIGURE 7.1 Cervical stenosis is a narrowing of the spinal canal that may be due to a variety of factors (e.g., congenital narrowing, osteophyte formation, and hypertrophy of the ligamentum flavum).

neuron signs, depending on the spinal level involved. Lower motor neuron findings are more commonly seen in the upper extremities; these include muscle atrophy, diminished sensation, decreased reflexes, diminished muscle tone, and weakness. Upper extremity myelopathic findings, such as hyperactive reflexes, increased tone, and present Hoffmann sign, can also be observed in cases of upper and mid cervical spinal cord involvement. A Spurling sign (radicular pain on axial loading of an extended head rotated toward the involved extremity) can also be present. A well-documented feature of cervical spondylotic myelopathy is so-called myelopathy hand, characterized by wasting of intrinsic and extrinsic hand muscles, loss of power of adduction and extension of the ulnar two or three digits, and inability to rapidly grip and release. Myelopathy hand is demonstrated by the hand grip-and-release test, which measures alternating closed-fist and full finger extension movements (normal result is 20 times in 10 seconds); the finger escape sign is tested with fingers fully extended and adducted, noting a tendency for ulnar digit spread [11].

Lower extremity examination is more consistent with upper motor neuron findings in the presence of cervical stenosis with myelopathy. Increased reflexes, Babinski sign, sustained or unsustained clonus, spasticity, weakness, decreased tactile and vibratory sensation, impaired proprioception, and neurogenic bowel or bladder can be seen. Lhermitte sign, an electric-like sensation that the patient reports going down the back when the neck is flexed (Fig. 7.2), can sometimes be elicited [12]. Refer to Chapter 1 for more detail.

Functional Limitations

The functional limitations depend on the extent of neurologic involvement. A person with mild symptoms can still be completely independent with activities of daily living, mobility, household chores, and work duties. In some cases, pain and weakness can produce various degrees of disability in self-care, such as grooming, bathing, and dressing, as well as in more physically demanding functions, especially in the community setting, such as lifting, carrying, and ambulation. Bowel and bladder incontinence as well as abnormalities of mood and sleep can further lead to social isolation and an increased level of actual and self-perceived disability.

FIGURE 7.2 Lhermitte sign. The examiner flexes the patient's head and hip simultaneously.

In extreme cases, paraplegia and quadriplegia can limit nearly all functional activities.

Diagnostic Studies

Facet and uncovertebral joint arthropathy, loss of intervertebral disc space, neuroforaminal narrowing, and presence of spondylolisthesis can be evaluated with cervical spine radiographs; if dynamic instability is suspected, flexion-extension views are advised. Presence of osseous and soft tissue disease as well as the extent of nerve root and spinal cord compression can be assessed by magnetic resonance imaging (MRI) (Fig. 7.3). Cervical myelography can provide additional information on the behavior of neural elements during flexion and extension. An upright dynamic MRI study may be able to provide the same information on the behavior of neural elements with less procedural invasiveness [13] (Fig. 7.4). Somatosensory evoked potentials can confirm the presence of myelopathy, and electromyography can confirm peripheral nerve root involvement [14].

Several radiologic criteria exist to define what constitutes significant stenosis of the cervical spine. The normal anterior-posterior dimension of the spinal canal at C3 through C7 is 16 to 18 mm [15]. Neck flexion reduces canal diameter by 2 to 3 mm, whereas extension

FIGURE 7.3 Severe C4-C5 cervical stenosis. Disc-osteophyte complex and hypertrophic ligamentum flavum are producing an indentation of the spinal cord. Notice an intramedullary hyperintensity signal consistent with spinal cord injury.

may decrease it up to 3.5 mm at 45 degrees because of ligamentum flavum infolding [16,17]. According to some sources, an absolute cervical spinal stenosis is present when the sagittal spinal canal diameter is less than 10 mm, and relative spinal stenosis is present when this measurement is 10 to 13 mm [18,19]. A Torg ratio of less than 0.8, which is measured by dividing the sagittal diameter of the spinal canal by the sagittal diameter of the respective vertebral body, has been used to predict the presence of significant spinal stenosis and tries to

eliminate any inherent radiographic measurement errors [20]. A more widely accepted approach in evaluating the extent of stenotic pathologic changes is through the use of MRI, which permits the functional capacity of the surrounding subarachnoid space and the state of the spinal cord itself to be more definitively assessed. Several studies have demonstrated a poor correlation between Torg ratio and extent of stenosis identified on MRI [21].

Diffusion-weighted sequences, in particular a technique known as diffusion tensor imaging, allow the visualization of specific nerve tract bundles and may detect early damage to the myelin sheath. Although its utility in imaging the spinal cord is currently limited, diffusion tensor imaging has demonstrated enhanced sensitivity for detection of early cervical spondylotic myelopathy and intramedullary lesions [22,23]. The presence of intramedullary signal abnormalities warrants further investigation and a more

Differential Diagnosis

- Thoracic spinal stenosis
- Cervical intramedullary or extramedullary neoplasm
- Cervical osteomyelitis with or without epidural abscess
- Multiple sclerosis (spinal)
- Transverse myelitis
- Cerebrovascular accident
- Syringomyelia
- Spinal cord injury
- Arteriovenous malformation
- Tabes dorsalis
- Progressive multifocal leukoencephalopathy
- Tropical spastic paraparesis
- Lumbar spinal stenosis
- Thoracic outlet syndrome
- Idiopathic brachial neuritis
- Brachial plexopathy

FIGURE 7.4 Sagittal magnetic resonance images of cervical spine with the patient recumbent (A) and standing with the neck extended (B).

aggressive treatment approach (see Fig. 7.3). Computed tomographic myelography continues to offer some advantages over MRI, including superior spatial resolution, ability to distinguish bone from soft tissue intrusion into the cervical foramina, and dynamic visualization of the flow of contrast material [24].

Treatment

Initial

Conservative treatment is generally undertaken in the absence of clinical evidence of cervical myelopathy. If cervical myelopathy is suspected or clearly evident, the patient must be immediately referred for an evaluation by a spine surgical specialist. When a patient is symptomatic with pain but does not have myelopathic symptoms, relative decrease in physical activity for no longer than 2 or 3 days is initially recommended. For severe cervical or radicular pain, a soft neck collar can be prescribed for a few days with subsequent self-weaning by alternating periods of collar removal [25].

Self-application of ice or heat for cervical pain and transcutaneous electrical nerve stimulation for radicular symptoms can be of benefit to some patients.

Initial analgesics of choice are acetaminophen and nonsteroidal anti-inflammatory drugs, which may show some effect in cervical as well as in radicular pain when they are taken at regular intervals. More than one family of nonsteroidals should be tried before they are deemed to be ineffective. A short course of opioids and muscle relaxants may benefit those patients with severe pain and strong contraindications to the use of acetaminophen and nonsteroidal anti-inflammatory drugs. For recalcitrant, functionally limiting radicular symptoms, a 7- to 10-day tapering course of oral steroids is recommended. Persistent radicular pain can be treated with neuropathic pain medications, such as gabapentin, pregabalin, tricyclic antidepressants, duloxetine, and others [26].

Education of the patient about the nature of cervical stenosis, its worrisome signs and symptoms (e.g., progressive difficulties with gait, urinary retention or incontinence), injury prevention, and the importance of staying active is of paramount importance. In older patients, fall prevention and fall precautions should be immediately addressed to prevent catastrophic neurologic consequences. In individuals with MRI evidence of severe cervical stenosis, certain physical activities, such as horseback or motorcycle riding, climbing ladders, and participation in contact sports, should be strongly discouraged. Patients should also be advised to avoid the extremes of repetitive cervical extension and flexion, as in swimming the breast stroke, painting a ceiling, or performing legs overhead backward stretching.

Rehabilitation

Physical and occupational therapy should focus on keeping patients as active as possible while educating them about activities that might place them at risk for further injury. Continued physical activity, such as walking and the use of a stationary bicycle, is recommended to prevent overall muscle and aerobic deconditioning. Gentle cervical traction may also be tried in the absence of severe stenosis or myelopathic findings. With passing of the acute phase, a program

consisting of stretching and isometric neck exercises should be undertaken. Once the pain-free range of motion is achieved, isotonic neck strengthening is initiated [27]. Eventually, patients should be graduated to a home exercise program.

Work site evaluation and institution of certain job restrictions are recommended to prevent repetitive hyperextension or hyperflexion activities. These might include adjustment of computer monitor height, recommendation for a phone headset, and restriction of duties requiring activities above eye level. The use of bifocals should also be addressed because these require frequent head positional changes.

Depression and anxiety can lead to symptom magnification and should be addressed by a mental health care provider. Cognitive-behavioral therapy, biofeedback, self-hypnosis, and relaxation techniques must always be considered part of the comprehensive pain management treatment.

Procedures

A trial of interlaminar or transforaminal epidural steroid injections is advocated for acute or subacute radicular symptoms of severe intensity unresponsive to more conservative measures. Care should be taken to avoid the introduction of a spinal needle at the level of stenosis when an interlaminar approach is used. Transforaminal epidural steroid injections should be performed by a well-trained practitioner with the use of digital subtraction angiography and with preference toward nonparticulate steroids (e.g., dexamethasone) to avoid catastrophic complications. Patients without significant central spinal canal compromise and who continue to suffer with chronic severe radicular symptoms, unresponsive to conservative approaches, may be candidates for a spinal cord stimulator trial and implantation.

Arthritic cervical facet joints, which are innervated by medial branch nerves, can be another source of pain. Intra-articular steroid injections can provide up to several months of significant pain relief. If these fail to provide significant analgesic effect, diagnostic medial branch nerve blocks can be performed; if results are found to be positive, radiofrequency nerve ablation should follow.

Surgery

Immediate surgical intervention should be sought with symptoms of progressive weakness, bladder or bowel incontinence, unsteady gait, and upper motor neuron findings. Decompressive single-level or multilevel laminectomy, laminoplasty, discectomy, foraminotomy, and cervical fusion by use of bone graft or instrumentation are the common surgical procedures. Referral to a surgical specialist should be considered for intractable radicular symptoms [28,29].

Various classification systems have been used to grade the severity of spondylotic myelopathy and to guide the decision for surgery. The Nurick scale, used more frequently in a research setting, is based exclusively on ambulatory function [30]. The Japanese Orthopaedic Association (JOA) classification system and its modified versions evaluate additional variables, including upper extremity function and manual dexterity, sensory changes of the trunk and extremities, and bladder function [31]. Operative management is typically recommended for a JOA score of less than 13 with clinical symptoms and evidence of spinal cord compression on imaging [32].

Potential Disease Complications

If it is left untreated, progressive pressure on the exiting cervical nerve roots and the spinal cord may lead to worsening weakness, loss of sensation, dysfunction of the bladder and bowel, or tetraplegia.

The natural course of symptomatic cervical spondylotic myelopathy, when it is treated conservatively, demonstrates slow gradual decline in many patients, with periods of long quiescence or mild clinical improvement in some [33].

Potential Treatment Complications

Application of aggressive or improper physical or occupational therapy treatments can lead to further injury to the already compromised spinal cord and the exiting nerve roots. Cervical traction may promote signs and symptoms of myelopathy and radiculopathy. Atrophy of cervical musculature can occur with prolonged use of a cervical collar [34]. Aggressive cervical manual technique can cause vertebral artery dissection and severe neurologic sequelae.

Nonsteroidal anti-inflammatory medications carry well-known side effects of gastrointestinal irritation, bleeding, edema, and nephropathy. These medications are to be used cautiously or avoided in patients with a past history of peptic ulcer disease or with decreased renal function. A proton pump inhibitor or misoprostol should be considered for ulcer prophylaxis in individuals at high risk. All of the neuropathic pain medications carry significant side effects; gabapentin and pregabalin possess the best tolerance. The most common complaints are sedation, dizziness, and poor ambulatory balance. Continued use of opioids can lead to physiologic dependence, tolerance, sedation, constipation, and rarely addiction. Objective evidence of improved function and decreased level of pain is required for their continued use.

Interlaminar epidural steroid injections carry a small risk of dural puncture and subsequent development of a post-dural puncture headache. In most patients, these headaches are self-limited and respond well to bed rest, hydration, and caffeine. Improper placement of the needle tip and intravascular injection of particulate steroids with the transforaminal epidural approach can lead to spinal cord injury, stroke, and brain stem infarct. All interventions, percutaneous and surgical, carry a rare risk of spinal infection, compressive hematoma, and nerve and spinal cord injury.

CHAPTER 8

Cervicogenic Vertigo

Joanne Borg-Stein, MD

Melissa Colbert, MD

Synonyms

Cervicogenic dizziness
Neck pain associated with dizziness

ICD-9 Codes

723.1 Neck pain
780.4 Vertigo
780.4 Dizziness

ICD-10 Codes

M54.2 Neck pain
R42 Vertigo
R42 Dizziness

Definition

Cervicogenic vertigo is the false sense of motion that is due to cervical musculoskeletal dysfunction. The symptoms may be secondary to post-traumatic events with resultant whiplash or postconcussive syndrome. Alternatively, cervicogenic vertigo may be part of a more generalized disorder, such as fibromyalgia or underlying cervical osteoarthritis.

Cervicogenic vertigo is thought to result from convergence of the cervical and cranial nerve inputs and their close approximation in the upper cervical spinal segments of the spinal cord [1,2]. Dizziness and vertigo, common presenting symptoms, account for 8 million primary care visits to physicians in the United States each year and represent the most common presenting complaint in patients older than 75 years [3]. In fact, 40% to 80% of patients with neck trauma experience vertigo, particularly after whiplash injury. The incidence of symptoms of dizziness and vertigo in whiplash patients has been reported as 20% to 58% [4,5].

Symptoms

Patients with cervicogenic vertigo experience a false sense of motion, often whirling or spinning. Some patients experience sensations of floating, bobbing, tilting, or drifting. Others experience nausea, visual motor sensitivity, and ear fullness [6]. The symptoms are often provoked or triggered by neck movement or sustained awkward head positioning [7–9]. Cervical pain or headache may interfere with sleep and functional activities. At times, patients with coexistent cervical radiculitis may complain of paresthesias in the upper cervical dermatomes.

Physical Examination

The essential elements of the physical examination are normal neurologic, ear, and eye examination findings for nystagmus. Abnormalities in any of these aspects of the examination indicate a need to exclude other otologic or neurologic conditions, such as Meniere disease, benign paroxysmal positional vertigo, and stroke [5,10]. A careful cervical examination should be performed, including range of motion testing and palpation of the facet joints to assess mechanical dysfunction. Myofascial trigger points should be sought in the sternocleidomastoid, cervical paraspinal, levator scapulae, upper trapezius, and suboccipital musculature. Patients with cervicogenic headache and disequilibrium have a significantly higher incidence of restricted cervical flexion or extension and painful cervical joint dysfunction and muscle tightness [11,12]. Palpation in these areas can often reproduce the symptoms experienced as cervicogenic vertigo [13].

Functional Limitations

Functional limitations may include difficulty with walking, balance, or equilibrium. As a result, patients may not feel confident with activities such as driving because cervical rotation may induce symptoms. Occupations that require balance and coordination (such as construction) are often limited. Anxiety about the occurrence of disequilibrium may contribute to secondary disability.

Diagnostic Studies

Cervicogenic dizziness is a clinical diagnosis. Testing may include cervical radiographs to rule out cervical osteoarthritis or instability. Cervical magnetic resonance imaging is indicated when cervical spondylosis is suspected, either as a cause of the condition or as an associated diagnosis. Brain magnetic resonance imaging or magnetic resonance angiography may be ordered to exclude vascular lesions or tumor (i.e., acoustic neuroma). A comprehensive neurologic test battery and consultation are preferred if a primary otologic disorder or post-traumatic vertigo is considered [14].

Differential Diagnosis

Meniere disease
Benign paroxysmal positional vertigo
Labyrinthitis
Vestibular neuronitis
Cardiovascular causes: arrhythmia, carotid stenosis, or postural hypotension
Vestibular migraine
Progressive dysequilibrium of aging
Post-traumatic vertigo

Treatment

Initial

Initial treatment involves reassurance and education of the patient. Nonsteroidal anti-inflammatory drugs are useful to help pain control for those who have underlying cervical osteoarthritis. Muscle relaxants such as cyclobenzaprine, carisoprodol, and low-dose tricyclic antidepressants may be used at bedtime to facilitate sleep and muscle relaxation for myofascial pain. We occasionally prescribe ondansetron (4 to 8 mg every 8 hours as needed) if disequilibrium is accompanied by significant nausea.

Rehabilitation

Rehabilitation is aimed at reducing muscle spasm, increasing cervical range of motion, improving posture, and restoring function. A physical therapist with training and experience in manual therapy, myofascial and trigger point treatment, and neck and trunk stabilization techniques should evaluate and treat the patient to restore normal cervical function [15]. The use of gentle manual therapy is validated by moderate evidence, with sustained natural apophyseal glides being particularly beneficial in relief of dizziness and pain up to at least 12 weeks [16,17]. Occupational therapy can improve posture, ergonomics, and functional daily activities [18]. Vestibular rehabilitation therapy helps patients develop compensatory responses and normalizes cervical sensory input [16].

Ergonomic accessories, such as telephone earset or headset, may help the patient avoid awkward head and neck postures that contribute to symptoms. Psychological or behavioral medicine consultation and treatment can aid

the patient in overcoming the fear, avoidance, and anxiety that often develop [16,19].

Procedures

Trigger point injections with local anesthetic (1% lidocaine or 0.25% bupivacaine) are often helpful to decrease cervical muscle pain (Fig. 8.1). The clinician should locate those trigger point areas that reproduce the patient's symptoms. Acupuncture with an emphasis on local treatment of muscle spasm may be an alternative to trigger point injection [20,21].

Although botulinum toxin injection may have a role in the treatment of cervicogenic headache [22,23], there are no data yet on the treatment of cervicogenic vertigo with botulinum toxin.

FIGURE 8.1 A and B, Trigger points in the splenius capitis muscle frequently involved in cervicogenic vertigo. (From Simons DG, Travell JG, Simons LS. *Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual*, 2nd ed. Upper Half of Body, vol 1. Baltimore, Williams & Wilkins, 1999:310.)

Surgery

There is no surgery indicated for treatment of this disorder, unless there is coexistent neurologically significant cervical stenosis or disc herniation.

Potential Disease Complications

The major complications are inactivity, deconditioning, falls, fear of going outside the home, anxiety, and depression. Chronic intractable neck pain and persistent dizziness may persist in spite of treatment.

Potential Treatment Complications

Side effects from nonsteroidal anti-inflammatory drugs may include gastric, renal, hepatic, cardiovascular, and hematologic complications [24]. Muscle relaxants and tricyclics may induce fatigue, somnolence, constipation, urinary retention, and other anticholinergic side effects. Local injections may result in local pain, ecchymosis, intravascular injection, or pneumothorax if they are improperly executed.

CHAPTER 9

Trapezius Strain

Atul T. Patel, MD, MHSA

Synonyms

Myofascial shoulder pain
Trapezius myositis
Myofasciitis
Tension neck ache
Nonarticular rheumatism
Fibrositis
Fibromyalgia
Repetitive stress injury

ICD-9 Codes

729.1 Myalgia and myositis, unspecified
847.0 Neck (sprain or strain); whiplash injury
847.1 Thoracic (sprain or strain)
847.9 Unspecified site of the back (sprain or strain)

ICD-10 Codes

M60.9 Myositis, unspecified
M79.1 Myalgia
S13.4 Whiplash injury (cervical spine)
S13.9 Neck sprain, unspecified parts of the neck
S16.1 Neck strain (add additional character for type of encounter)
S23.3 Thoracic sprain
S39.012 Back strain

Definition

Trapezius strain is often considered a part of the myofascial pain syndrome (MPS). This is a common diagnosis of patients who present to outpatient clinics for musculoskeletal pain disorders [1]. There is no standard definition of trapezius strain or MPS; however, MPS is described as a disorder characterized by acute and chronic nonspecific

pain that affects a small number of muscles and involves single or multiple trigger points that are usually located in tight bands within the affected muscles [2]. The pain in this area must not be mistaken for cervical radicular pain that involves the shoulder girdle and the upper limb [3]. The etiology of trigger point formation is not known, but the most accepted hypothesis focuses on the existence of dysfunctional end plates leading to a perpetuated shortening of the muscle [4,5].

Trapezius strain is thought to be due to common repetitive strain or stress injury associated with carrying light loads and certain postures, such as that with working on a computer for long periods [6]. Myofascial trigger points can be the main cause of neck and upper back pain, and the trapezius muscle is the most commonly studied [7]. The condition can also result from acute causes, such as a whiplash injury.

Symptoms

Patients typically complain of a sore or aching sensation in the region of the upper trapezius muscle. Patients may also complain of posterior neck and shoulder pain. Some may have associated posterior headaches, difficulty with sleeping due to shoulder pain, and interscapular area pain. The symptoms can be constant and relieved by rest and worsened with activity. There can be increased pain with cervical movement and hence limitation in neck range of motion. The pain is regional and does not follow spinal segmental or peripheral nerve distribution. Patients may often report that the symptoms are partly relieved with the use of heat or cold modalities and focal pressure.

Physical Examination

The importance of the physical examination is to rule out other conditions that may be causing the patient's symptoms, such as a radiculopathy, peripheral nerve injury, cervical dystonia, or some other condition that may be suspected on the basis of the history. A neurologic and musculoskeletal examination focusing on the neck and upper body should be done in addition to a general examination. Other evaluations include cranial nerve function, especially checking the spinal accessory nerve; sensation to light touch and pinprick about the face, upper limbs, and torso with attention to dermatomes and cutaneous nerve distribution; muscle stretch reflexes; and strength testing. The findings on neurologic examination are typically normal in primary trapezius

strain. The patient may present with a forward head posture, scapular protraction, and compensatory cervical hyperextension. Muscle palpation about the neck and shoulder girdle may reveal tender areas and trigger points, especially in the trapezius muscle. A shoulder examination should be carried out to assess for shoulder disease.

Functional Limitations

Trapezius muscle strain can limit activities requiring the arm to be outstretched in front or to the side. There can be pain with rotation of the head and hence function limitation, such as turning the head for a shoulder check when driving. Pain in certain positions may interfere with restful sleep and thus affect overall function.

Diagnostic Studies

There is no specific test that is used to diagnose trapezius strain. It is a clinical diagnosis based on the history and physical examination. Radiologic studies, electrodiagnostic testing, and laboratory testing can be helpful in ruling out other potential conditions, such as cervical radiculopathy, cervical degenerative disease, shoulder disease, or inflammatory process. Newer musculoskeletal imaging techniques show promise for future application as diagnostic tools to objectively measure the presence or absence of myofascial trigger points. Magnetic resonance elastography is a research tool that is used to measure the stiffness of biologic tissues; it has been reported to successfully identify and quantify myofascial taut bands [8]. Musculoskeletal ultrasound is another tool that is changing the approach to the diagnosis of musculoskeletal conditions, including muscle strains [9,10].

Differential Diagnosis

Cervical spondylosis
Cervical herniation
Cervical radiculopathy
Cervical facet syndrome
Peripheral nerve entrapment (e.g., suprascapular, spinal accessory)
Inflammatory disease (e.g., myositis, polymyalgia rheumatica)
Endocrine disorders (e.g., hypothyroidism)
Electrolyte abnormalities
Tumor

Treatment

Initial

Initially, the patient should be educated about the condition and its usual benign course. The importance of appropriate activity, posture, and exercise is stressed. The goal is to break the cycle of improper posture, overuse and strain, and deconditioning. This may require a short-term course of muscle relaxants, anti-inflammatory medications, analgesics, and modalities.

There is little evidence in the literature that any of the muscle relaxants provide clear benefit in patients with MPS.

A Cochrane review that evaluated the efficacy of cyclobenzaprine for the treatment of MPS found that insufficient evidence supports its use because of a lack of high-quality randomized controlled trials [11]. A review article that assessed the efficacy of numerous muscle relaxants for the treatment of MPS concluded that insufficient evidence exists to support the use of tizanidine, alprazolam, or diazepam monotherapy, but evidence is supportive for the use of clonazepam in the treatment of MPS [12]. Similarly, there is insufficient evidence in favor of antidepressants (other than amitriptyline), anticonvulsants, topical analgesics, nonsteroidal anti-inflammatory medications, and other analgesics [13].

Electrical stimulation, laser therapy, and magnetic therapy did not show clear evidence to support use in the treatment of MPS. Ultrasound-based interventions appear to have a role in providing short-term and intermediate-term improvement in pain and function, especially as an adjunctive therapy [13].

Rehabilitation

The goals of therapy (occupational or physical) are to reduce pain and to improve function. Depending on the severity and chronicity of the condition, the patient may have developed secondary problems related to muscle shortening, weakness, and reduced range of motion. The initial goal of the therapy is to reduce the local muscle spasms and pain, followed by appropriate stretching and strengthening to minimize the risk of recurrent problems. Physical modalities such as heat and cold therapy combined with massage can help relieve some of the symptoms by relaxing the muscles. Stretching is initially targeted to specific portions of the trapezius muscle. The cervical extensor and scapular stabilizers are strengthened. The patient should be set up with a home program to continue with the stretching and strengthening exercises. A primary goal of rehabilitation should include evaluating and appropriately modifying tasks that exacerbate the patient's symptoms. For example, carrying heavy baskets of laundry, driving, typing on a computer keyboard, and many other daily tasks may exacerbate symptoms. If indicated, an ergonomic assessment of the patient's workstation should be carried out to help maintain an appropriate upper body posture.

Procedures

Procedures include acupuncture, dry needling, and trigger point injections. A review of dry needling therapy trials in patients with MPS shows inconclusive evidence in favor of or against the use of superficial dry needling therapy for the treatment of MPS [13]. There is insufficient evidence to conclude that trigger point injections are more effective than dry needling alone or placebo. Limited evidence exists to support the use of trigger point injections for the treatment of MPS (grade B recommendations) [13]. Botulinum toxin injections have been studied. A Cochrane review found that only one of several trials that met the selection criteria was effective in treating pain from trigger points [14–17]. The conclusion of this review was that current evidence does not support the use of botulinum toxin A for the

treatment of trigger points in MPS [18]. Another review of predominantly level 1 studies found three studies in favor of botulinum toxin injections and eight against or equivalent with control intervention or placebo [13].

Surgery

Surgery is not indicated for treatment of trapezius strain.

Potential Disease Complications

If the patient's condition is left untreated, problems of reduced range of functional motion of the neck and shoulder, muscle atrophy, and secondary chronic pain may develop. These can result in personal and occupational disability.

Potential Treatment Complications

Oral medications that may be used for analgesia or muscle relaxation can have side effects or interactions with other drugs the patient may be taking. The nonsteroidal anti-inflammatory drugs may produce gastropathy, renal toxicity, hepatic toxicity, bleeding, exacerbation of asthma, and central nervous system effects. Muscle relaxants and tricyclic antidepressants may cause sedation and anticholinergic side effects, such as dry mouth, urinary retention, orthostatic hypotension, and weight gain. Botulinum toxins can cause asthenia, dysphagia, influenza-like symptoms, and muscle weakness. Trigger point injections can result in local ecchymosis and pain.

ICD-9 Codes

831.04 Closed dislocation acromioclavicular joint
840.0 Acromioclavicular (joint) (ligament) sprain

ICD-10 Codes

S43.50 Sprain of unspecified acromioclavicular joint, ligament
S43.51 Sprain of right acromioclavicular joint, ligament
S43.52 Sprain of left acromioclavicular joint, ligament
S43.101 Unspecified dislocation of right acromioclavicular joint
S43.102 Unspecified dislocation of left acromioclavicular joint
S43.109 Unspecified dislocation of unspecified acromioclavicular joint
Add seventh character for episode of care (A—initial encounter, D—subsequent encounter, S—sequela)

Definition

The acromioclavicular joint is a diarthrodial joint found between the lateral end of the clavicle and the medial side of the acromion [1]. The joint is surrounded by a fibrous capsule and stabilized by ligaments. The acromioclavicular ligaments cross the joint. Three ligaments begin at the coracoid process on the scapula and attach to the clavicle (trapezoid and conoid ligaments) or the acromion (coracoacromial ligament) (Fig. 10.1). This complex provides passive support and suspension of the scapula from the clavicle while allowing rotation of the clavicle to be transmitted to the scapula [1,2].

Injuries to the acromioclavicular complex are graded I to VI (Table 10.1). Injuries to the acromioclavicular joint were originally classified as grades 1, 2, and 3 by Tossy [3]. This classification was extended to include more complicated injuries, and grades 4, 5, and 6 were described. The extended grading system uses roman numerals [4].

The coracoacromial (lateral) ligament is not disrupted in injuries to the acromioclavicular joint. Therefore the fibrous connection persists between structures of the scapula emanating anteriorly and posteriorly [5]. In rare instances, there is an intra-articular fracture of the distal clavicle in addition to the ligamentous injuries [6].

There are few demographic data on differences of the disorder based on gender. Problems with the acromioclavicular joint can be associated with trauma and with overhead and throwing activities. Higher grade injuries are more likely to be due to trauma, such as auto accidents, falls, or sports injuries [7]. Concomitant injuries can vary on the basis of age; 86% of individuals older than 50 years have rotator cuff tears [8].

Most patients with grade I or grade II injuries respond to conservative measures and become asymptomatic within 3 weeks [9].

Symptoms

Patients often provide a history of trauma to the shoulder or in the vicinity of the acromioclavicular joint. Participants in

FIGURE 10.1 Normal anatomy of the ligaments associated with the acromioclavicular joint.

contact or collision sports (e.g., football, downhill skiing) are particularly susceptible. Patients seek care because of pain in the anterior and superior aspect of the shoulder [2]. This radiates into the base of the neck and the trapezius or deltoid muscles or down the arm in a radicular pattern [2,5,10].

Patients may describe pain brought on by activities of daily living that bring the arm across the chest (e.g., reaching into a jacket pocket) or behind the back (e.g., tucking in a shirt). Pain can also occur with shoulder flexion (reaching overhead) or with adduction of the arm across the chest. Patients may not have pain at rest and may be able to complete many activities without discomfort.

Physical Examination

Appropriate examination for suspected acromioclavicular injuries includes an examination of the neck and shoulder joint and girdle to eliminate the possibility of a radiculopathy or referred pain. Patients should have normal neck and neurologic examination findings. The presence of neurologic or vascular injury suggests that a greater degree of trauma has been sustained [5].

On inspection, there may be a raised area at the acromioclavicular joint. This is caused by depression of the scapula relative to the clavicle or swelling of the joint itself. This area is commonly tender to touch. On active range of

motion, the patient may complain of pain or wince near the extreme of shoulder flexion.

Shoulder range of motion is typically within normal limits. Supporting the arm at the elbow and gently directing the arm superiorly may decrease the pain and allow more complete assessment of the patient's shoulder range of motion. The pain may become worse as the shoulder is further flexed, whether it is done actively or passively. This is in distinction to impingement syndromes, which often hurt at a particular point in the arc of motion but are painless as the motion proceeds. Pain is typically absent with static manual muscle testing of the rotator cuff. Rotator cuff injuries will be painful with activation of the muscles of the rotator cuff. These problems are best identified with the shoulder in a neutral position (i.e., elbow next to the body) because the rotator cuff muscles are in a lengthened position and are easily made symptomatic.

Special tests to identify acromioclavicular joint disease attempt to compress the joint. The most common test is the cross-body adduction test (Fig. 10.2). The shoulder is abducted to 90 degrees and the elbow is flexed to the same degree. The clinician then brings the arm across the patient's body until the elbow approaches the midline (or the patient reports pain) [2].

FIGURE 10.2 Cross-body adduction test for a sprain of the acromioclavicular joint.

Table 10.1 Grades of Acromioclavicular Joint Injuries and Treatments

Grade of Injury	AC Ligament	CC Ligament	Clavicle Displacement	Treatment
I	Sprain	Intact	Mild superior displacement	Conservative
II	Torn	Sprain	Definite superior displacement	Conservative
III	Torn	Torn	25%-100% increase in CC space	Conservative or surgical
IV	Torn	Torn	Posterior displacement	Surgical
V	Torn	Torn	100%-300% increase in CC space	Surgical
VI	Torn	Torn	Subacromial or subcoracoid location	Surgical

AC, acromioclavicular; CC, coracoclavicular.

Other tests help differentiate between impingement syndrome and acromioclavicular joint pain. If the shoulder is passively flexed while it is internally rotated, the greater tuberosity can pinch (impinge) the supraspinatus tendon and subacromial bursa. The same test performed with the shoulder externally rotated will compress the acromioclavicular joint without impinging the subacromial space [11]. In the active compression test, the shoulder is flexed to 90 degrees and then adducted to 10 degrees (Fig. 10.3). The patient first maximally internally rotates the arm and then tries to flex the shoulder against the clinician's resistance. This puts pressure on the acromioclavicular joint and may reproduce pain if disease is present. The test is repeated with the shoulder in full external rotation. This will put

FIGURE 10.3 The active compression test. **A**, The arm is forward flexed and internally rotated maximally. Downward force is applied, and pain indicates acromioclavicular joint disease. **B**, The test is repeated with the arm externally rotated. Pain indicates disease of the biceps tendon and its labral attachment. (From O'Brien SJ, Pagnani MJ, Fealy S, et al. The active compression test: a new and effective test for diagnosing labral tears and acromioclavicular joint abnormality. *Am J Sports Med* 1998;26:610-613.)

stress on the biceps tendon and its labral attachment while excluding the acromioclavicular joint [12].

In the acromioclavicular resisted extension test, the shoulder is abducted to 90 degrees and adducted across the body to 90 degrees (Fig. 10.4). The examiner resists active shoulder extension. A positive test result reproduces pain in the acromioclavicular joint. A combination of these tests will improve the diagnostic accuracy over isolated tests [13].

The Paxinos sign, along with bone scan, has a high degree of diagnostic accuracy in acromioclavicular joint disease [14]. The examiner stands behind the patient and, using the hand contralateral to the affected shoulder, stabilizes the clavicle and pushes the acromion into the clavicle with the thumb. The test response is considered positive if pain occurs or increases in the region of the acromioclavicular joint; the test response is considered negative if there is no change in the pain level (Fig. 10.5).

Functional Limitations

Reaching up, reaching across the body, and carrying heavy weights are limited because of pain. Patients may have no pain at rest and little or no pain with many activities. Patients may complain of difficulty with putting on a shirt, combing the hair, and carrying a briefcase or grocery bag. Most recreational activities, especially those that incorporate throwing, will be limited as well. Sleep may be affected because of pain, especially when rolling over on the affected side.

Diagnostic Studies

Because this is often a traumatic injury, radiographs are important in most cases and should be obtained to rule out fracture as well as to assess the severity of the injury (Fig. 10.6). Views should include an anteroposterior view, a lateral Y view, and an axillary view. It is important to let the radiologist know that injury to the acromioclavicular joint, not just the shoulder, is in question. Stress or weighted views are usually not helpful and cause undue pain without improving the accuracy of diagnosis [2,15]. Overpenetration of films may make the interpretation of the acromioclavicular joint and distal clavicle difficult [5].

A 15-degree cephalad anteroposterior view helps diagnose sprains by decreasing x-ray penetration and showing separation between the acromion and clavicle, whereas the 40-degree cephalic tilt anteroposterior view should be used for suspected fractures of the clavicle. If the fracture is medial to the coracoclavicular ligaments, both anterior and posterior 45-degree views should be obtained [5]. Typically, the decision to obtain these views is made by a radiologist.

Certainly, if there are concerns about a fracture or arthrosis and the x-ray images do not provide confirmation, further evaluation with a bone scan [2,5] or magnetic resonance imaging (MRI) may be indicated [16]. MRI evaluation of symptomatic acromioclavicular joints revealed that 80% had active bone edema in the distal clavicle or acromion or on both sides, but no asymptomatic patients had this finding [17]. MRI will detect the extent of acromioclavicular arthrosis more frequently than conventional radiology [18]. MRI does not appear to add any further information to the clinical assessment [19].

FIGURE 10.4 In the acromioclavicular resisted extension test, the examiner resists active shoulder extension. A positive test result reproduces pain in the acromioclavicular joint. (From Chronopoulos E, Kim TK, Park HB, et al. Diagnostic value of physical tests for isolated chronic acromioclavicular lesions. *Am J Sports Med* 2004;32:655-661.)

FIGURE 10.5 To elicit the Paxinos sign, stand behind the patient and use the hand contralateral to the affected shoulder. (From Walton J, Mahajan S, Paxinos A, et al. Diagnostic values of tests for acromioclavicular joint pain. *J Bone Joint Surg Am* 2004;86:807-812.)

Ultrasonography is a reproducible method of evaluating the joint space and joint capsule, but the measurements may vary from those obtained by MRI [20]. The findings on ultrasound evaluation correlate well with the diagnosis obtained by clinical examination and radiography [21].

FIGURE 10.6 Grade III acromioclavicular joint dislocation. There is marked superior displacement of the distal clavicle relative to the acromion and coracoid processes. (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

Differential Diagnosis

- Adhesive capsulitis
- Arthritis (e.g., rheumatoid, crystal induced, and septic)
- Calcific tendinitis
- Cervical radiculopathy
- Distal osteolysis of the clavicle
- Fractures of the acromion or distal clavicle
- Ganglia and cysts in the acromioclavicular joint
- Gout
- Infection
- Os acromiale syndrome
- Rotator cuff tears
- Shoulder impingement syndrome
- Tendinitis of the long head of the biceps
- Tears of the glenohumeral labrum
- Tumors
- Referred pain may come from cardiac, pulmonary, and gastrointestinal disease

Treatment

Initial

Initial treatment depends on the degree of injury and the patient's activity and goals.

Type I and type II injuries are exclusively treated nonoperatively, whereas type IV, type V, and type VI injuries require surgery. Treatment of type III injuries is controversial (see Table 10.1).

The initial phase of treatment for all injuries not going to surgery (i.e., type I, type II, and some type III) includes rest, ice, and possibly a sling or brace for 1 to 6 weeks (2 to 3 weeks average). Over-the-counter or prescription non-narcotic analgesics are usually sufficient. Nonsteroidal anti-inflammatory drugs can be used for pain and inflammation. Injections into the joint can also be done in the initial phase of treatment for immediate pain control and to help confirm the diagnosis. Injections have been done acutely with immediate return to activity in low-grade injuries.

Rest should be relative, that is, the patient should avoid aggravating activities but should not be immobilized if at all possible.

Ice massage can be done over the painful area for 5 to 10 minutes every 2 hours, as needed. An ice pack can be used for 20 minutes at a time and also can be repeated every 2 hours. The usual precautions for the use of cold modalities should be followed.

Type I and type II sprains can be treated with a sling to help support the arm and shoulder. This should be used symptomatically and discontinued for painless activities and when the patient's pain is under control.

Type III injuries have been treated operatively and nonoperatively (Fig. 10.7). In the majority of published studies and reference texts, orthopedists favor nonoperative treatment as a rule, even in throwing athletes [5,15,22–24]. One study suggested greater long-term satisfaction in patients who had surgery but showed no difference in range of motion or strength [25]. Most patients have no long-term difficulty with nonoperative management. There are also reports of high complication rates with surgery [5,24]. Surgery may be considered in symptomatic individuals with type III injuries and in those who do not respond to conservative measures.

One approach for type III injuries is to treat conservatively with relative rest, support, modalities, medications for symptoms, and gradual return to activity during 6 to 12 weeks. If there is a significant limitation in function, including avocational or sport activities, or if the patient is not progressing as expected, further evaluation is warranted [5]. Unlike with musculotendinous injuries, delayed surgery does not lead to poorer outcomes.

Rehabilitation

Physical or occupational therapy can be ordered to assist with education of the patient, pain control, and, in later stages, gradual range of motion and strengthening exercises. Modalities to control pain can include, in addition to ice, ultrasound and phonophoresis with 10% lidocaine. Alternatively, interferential current can be used. As pain is controlled, motion can be obtained in a pain-free range. Codman and pendulum exercises can progress to active or active-assisted range of motion to restore shoulder flexion

FIGURE 10.7 Grade III acromioclavicular joint sprain. (From Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

and abduction, both individually and in combination. In the initial phase of a rehabilitation program, it is reasonable to avoid painful positions or movements. These include extremes of flexion—even when they are done passively—and adduction across the chest. When the shoulder is pain free and has full range of motion, rehabilitation can progress to gradual strengthening and return to activity. A typical shoulder strengthening rehabilitation program can be used. Light dumbbell exercises with 1 to 5 pounds to strengthen the internal and external rotators or resistance bands can be used initially. This program can be advanced to isolate the shoulder abductors and to incorporate internal and external rotator strengthening at different degrees of shoulder abduction. Further progression depends on the patient's goals and requires incorporation of the scapular stabilizers and training in coordinated movements.

Postoperative rehabilitation varies by the type of injury (type III–type VI), acute versus chronic repair, surgical technique employed, and surgeon. Typically, there is a period of immobilization or support with a sling (1–6 weeks). Passive, active-assisted, or active range of motion exercises may be allowed during this time. In some instances, daily activities will be allowed, but strengthening and heavy lifting are not.

Strengthening exercises may begin as soon as 2 weeks or as many as 3 months postoperatively, depending on the repair. Return to sports may take 8 weeks and be as long as 6 months. Given the variety of recommendations, good communication with the orthopedic surgeon is essential [7,26–28].

Procedures

Patients with acromioclavicular joint pain due to type I or mild type II injuries can receive injections and return to play or work during the same day or competitive event with little risk of injury as long as they have full functional range of motion and symmetric strength. For diagnostic purposes, a local anesthetic injection may confirm the diagnosis of a type I sprain if the patient has complete pain relief immediately after the injection. Intra-articular injection of a combination of a local anesthetic and a corticosteroid may give immediate and longer acting relief. Injections into the joint can be done for higher grade injuries as well as to give quick symptomatic relief. However, this is not a substitute for relative rest in more seriously injured joints (type II and higher), and 1 week of avoiding provocative maneuvers after the injection is advised [2]. The blind or palpation approach to acromioclavicular joint injection is done with the patient sitting or supine with the shoulder propped under a pillow. The acromioclavicular joint is injected under sterile conditions with use of a 25-gauge, 1½-inch disposable needle and a local anesthetic or anesthetic and corticosteroid combination (Fig. 10.8). Typically, a 1- to 3-mL aliquot of solution is injected (e.g., 1 mL of 1% lidocaine mixed with 1 mL of betamethasone). Keep in mind that the acromioclavicular joint is small and close to the surface.

Ultrasound guidance of the acromioclavicular joint injection can improve the accuracy of the injection [29,30]. Injection by the palpation method is truly in the joint 40% to 60% of the time [29,31]. Use of ultrasound [29,30] or an image intensifier [31] ensures 100% accurate needle placement.

FIGURE 10.8 Internal anatomic site for injection of the acromioclavicular joint. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

It is not clear that use of ultrasound improves outcome [30]. The ultrasound-guided approach is somewhat different (Fig. 10.9) as a lateral to medial approach is advocated [29].

Postinjection care should include local icing for 10 to 15 minutes and instructions to the patient to avoid aggravating activities for at least 1 week.

Surgery

Type IV, type V, and type VI injuries are forms of dislocation of the acromioclavicular joint. These need to be reduced surgically with some form of reconstruction attempted. Early referral is indicated to minimize pain and dysfunction. Because the scapula is no longer suspended from the clavicle, the deltoid and trapezius muscles will become involved in an attempt to hold the scapula in place. These muscles may have been injured directly and therefore are ill-suited to take on the role of suspending the arm. The result is more significant pain and a greater chance for prolonged disability.

If the patient has sustained a fracture, surgery may be necessary, and referral to an orthopedist is appropriate. The severity of the injury depends on whether the fracture is medial to the coracoclavicular ligaments or involves the acromioclavicular joint itself. Fractures medial to the ligaments can result in displacement of the clavicle, and the patient therefore runs the risk of delayed union or nonunion. The displacement can look like a type II or type III sprain. Careful examination of the location and degree of pain should suggest an injury to the clavicle. Regardless, radiographs are indicated to assess the possibility of fracture.

Fractures into the joint are likely to lead to arthrosis in the future. These patients may not need surgery initially—that will be decided by the patient and the orthopedist—but may require a protracted conservative course of symptomatic treatment.

Resection of the distal clavicle, tacking of the acromion to the clavicle, re-creation of the ligaments, and screw fixation of the acromioclavicular joint or of the clavicle to the coracoid process have been used to stabilize the joint. The goal of any surgical procedure is to try to re-create a stable, pain-free joint [5].

FIGURE 10.9 A, Needle approach and ultrasound transducer position for ultrasound-guided acromioclavicular joint injections. B, Ultrasound image of the acromioclavicular joint (asterisk) and needle (arrowheads) in long-axis (in-plane) view. Left, lateral; top, superficial, A, acromion, C, clavicle. (Merlin 1101 US system, B-K Medical Systems, Wilmington, Mass.) (From Peck E, Lai J, Pawlina W, Smith J. Accuracy of ultrasound-guided versus palpation-guided acromioclavicular joint injections: a cadaveric study. *PM R* 2010;2:817-821.)

Postoperative outcome of surgical repair of type V injuries was excellent in 11 of 12 patients after 2 years [7]. Twenty-one years after surgical treatment of type III injuries, 92% of patients had satisfactory results and no pain and would have the procedure again [32].

Potential Disease Complications

Patients may be left with a “bump” due to the depression of the acromion relative to the clavicle. This should be expected and is unavoidable without surgery. Acromioclavicular joint pain due to chronic instability is the most common complication [5,33]. Degenerative arthritis can occur because of the injury or instability. This can be treated symptomatically with modalities and injections. One in five patients with a grade I or grade II injury will have restriction in range of motion, but less than 10% will have symptoms that restrict daily or athletic activity [34].

If the pain persists, surgery should be considered. In one study, more than 25% of patients with grade I or grade II injuries required surgery 2 years after the injury [10].

Concomitant disorders of the glenohumeral joint complex can develop along with acromioclavicular arthrosis. These include rotator cuff tears, glenoid labrum tears, glenohumeral arthrosis, and biceps tendon disease [9].

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Cyclooxygenase 2 inhibitors may have fewer gastric side effects, but cardiovascular risks should be considered. Injection of the joint with too long a needle may result in injection into the subacromial space. This can cause diagnostic confusion, if not outright injury [2]. Injections can also be associated with infection in rare cases.

Direct complications of surgery can include infection, pain, wound or skin breakdown, and hypertrophic scar [5,23,35]. After surgery, there can be a recurrence of the deformity [23,25], hardware failure or migration [6,23,32,35], or limitation of movement. Pain may persist as a result of insufficient resection, weakness, or joint instability [2]. Acromioclavicular arthrosis may develop after surgery, although this may not adversely affect the patient's function [7,32].

Recalcification after acromioclavicular joint resection can be a cause of pain and may require revision of the distal clavicle resection [35]. Likewise, distal osteolysis of the clavicle can occur, requiring revision surgery [36]. Coracoclavicular ligament ossification may develop, although this is not typically painful [32].

Adhesive Capsulitis

Brian J. Krabak, MD, MBA, FACS

Synonyms

Frozen shoulder
 Periarthritis of the shoulder
 Stiff and painful shoulder
 Periarticular adhesions
 Humeroscapular fibrositis

ICD-9 Code

726.0 Adhesive capsulitis of shoulder

ICD-10 Codes

M75.00 Adhesive capsulitis of shoulder, unspecified
 M75.01 Adhesive capsulitis of right shoulder
 M75.02 Adhesive capsulitis of left shoulder

Definition

Primary adhesive capsulitis of the shoulder is an idiopathic, progressive, painful but self-limited restriction of active and passive range of motion [1–3]. The onset is insidious and progresses through several stages, usually during the course of 1 to 2 years. These stages include the painful phase, the freezing or adhesive phase, and the thawing or resolution phase. Adhesive capsulitis occurs in approximately 2% to 5% of the general population and accounts for approximately 6% of office visits to shoulder specialists (orthopedists and physiatrists) on a yearly basis [2]. The condition preferentially affects women after the age of 50 years, involves the nondominant shoulder, and develops in the opposite shoulder in 20% to 30% of cases. The primary etiology is unknown, but it is associated with numerous secondary causes, including immobilization, diabetes, hypothyroidism, autoimmune disease, and treatment of breast cancer (Table 11.1).

The pathologic process related to adhesive capsulitis involves structures both intrinsic to the glenohumeral joint and surrounding it (Fig. 11.1). Although it is not clear, one theory

is that stimulation of synovitis leads to fibrosis due to the activation of various cytokines, including growth factors such as transforming growth factor- β [4]. The pathologic findings of adhesive capsulitis ultimately depend on its stage when it is assessed [1,2]. The painful phase is characterized by synovitis that progresses to capsular thickening (particularly in the anterior and inferior portions of the capsule) with an associated reduction in synovial fluid. As the adhesive phase continues, fibrosis of the capsule is more pronounced, and thickening of the rotator cuff tendons is common. As this phase continues, the glenohumeral joint space becomes contracted and often obliterated. Pathologic change is more consistent with chronic inflammation with resolution of joint space loss during the final stage.

Symptoms

Symptoms will depend on the stage of adhesive capsulitis. In stage 1, the patients experience the gradual onset of progressive pain that is worse during the night and exacerbated by overhead activities. They will gradually report a loss of motion with symptoms lasting less than 3 months. In stage 2, there is a progressive increase in pain that is associated with a reduction in the range of motion and decreased use of the affected shoulder [1,2]. The stage can last 9 to 15 months. Stage 3, the “thawing stage,” is characterized by a gradual decrease in pain and increase in the pain-free range of motion. Some individuals will return to normal, but not all (Table 11.2).

Physical Examination

The findings noted on physical examination reflect the stage of adhesive capsulitis development. During the painful and adhesive stages of adhesive capsulitis, there is a measurable reduction in *both* passive and active shoulder range of motion. Motion is painful, particularly at the extremes of external rotation and abduction [1,2,5]. This pattern of motion loss is consistent with a capsular pattern of passive range of motion loss, which demonstrates a greater limitation in external rotation and abduction followed by an increasing loss of flexion. These signs are similar to those found in osteoarthritis of the glenohumeral joint, in which there is a similar loss of motion with shoulder pain. However, this presentation is in contrast to findings seen in rotator cuff tears, in which active range of motion is restricted but passive range of motion may approximate normal values. A reduced glenohumeral glide is often noted with adhesive capsulitis, especially with

Table 11.1 Diseases and Conditions Associated with Secondary Adhesive Capsulitis

Immobilization	Pulmonary tuberculosis	Scleroderma
Diabetes mellitus	Chronic lung disease	Post mastectomy
Thyroid disease	Myocardial infarction	Cervical radiculitis
Rheumatoid arthritis	Cerebrovascular accidents	Peripheral nerve injury
Trauma	Rotator cuff disease	Lung cancer
		Breast cancer

Modified from Siegel LB, Cohen NJ, Gall EP. Adhesive capsulitis: a sticky issue. *Am Fam Physician* 1999;59:1843-1852.

FIGURE 11.1 Relevant anatomy of the glenohumeral joint. Note the rotator cuff tendon insertion sites, biceps tendon, subacromial bursa, and coracoacromial ligament (CAL); the subcoracoid triangle is formed by the coracoid process, coracohumeral ligament (CHL), and joint capsule. (From Stubblefield MD, Custodio CM. *Upper extremity pain disorders in breast cancer*. *Arch Phys Med Rehabil* 2006;87[Suppl 1]:S96-S99.)

inferior translation. The relationship of glenohumeral joint movements independent of scapulothoracic motion should also be noted. Last, the shoulder is often painful to palpation around the rotator cuff tendons distally. As symptoms start to improve and the patient enters the resolution stage, there is a reversal of the loss of motion, with internal rotation being the last to improve.

Table 11.2 The Three Stages of Adhesive Capsulitis**Painful Stage**

Pain with movement
Generalized ache that is difficult to pinpoint
Muscle spasm
Increasing pain at night and at rest

Adhesive Stage

Less pain
Increasing stiffness and restriction of movement
Decreasing pain at night and at rest
Discomfort felt at extreme ranges of movement

Resolution Stage

Decreased pain
Marked restriction with slow, gradual increase in range of motion
Recovery is spontaneous but frequently incomplete

Modified from Siegel LB, Cohen NJ, Gall EP. Adhesive capsulitis: a sticky issue. *Am Fam Physician* 1999;59:1843-1852.

Neurologic evaluation findings are usually normal in adhesive capsulitis, although manual muscle testing may detect weakness secondary to pain or disuse. However, concomitant rotator cuff involvement is common and could explain true weakness if it is noted on physical examination. The combination of myotomal weakness, altered dermatomal sensation, reflex asymmetry, and positive findings with cervical spine provocative testing is more suggestive of a neurologic cause of shoulder pain [5].

Functional Limitations

Patients often experience sleep disruption as a result of pain or inability to sleep on the affected side. Inability to perform activities of daily living (e.g., fastening a bra in the back, putting on a belt, reaching for a wallet in the back pocket, reaching for a seat belt, combing the hair) is common. Work activities may be limited, particularly those that involve overhead activities (e.g., filing above waist level, stocking shelves, lifting boards or other items). Recreational activities (e.g., difficulty serving or throwing a ball, inability to do the crawl stroke in swimming) are also affected.

Diagnostic Studies

Because adhesive capsulitis is associated with other comorbidities and a population of patients in whom neoplastic processes are common, routine blood work and radiographs should be obtained to rule out secondary causes [6-9]. Radiographs in patients with adhesive capsulitis are generally normal. In advanced stages, joint space narrowing may be noted on arthrograms as there is a reduced volume of injectable contrast material into the joint (Fig. 11.2). Magnetic resonance imaging may also prove to be a useful diagnostic tool; studies have confirmed findings seen at arthroscopy, including thickening of the coracohumeral ligament and obliteration of the subcoracoid space (Fig. 11.3) [6-8]. Ultrasonography allows a dynamic view of the shoulder region with a sensitivity of 91%, a specificity of 100%, and an accuracy of 92% for detection of adhesive capsulitis [9].

Differential Diagnosis

Labral disease
 Rotator cuff disease
 Subacromial bursitis
 Osteoarthritis
 Acromioclavicular joint disease
 Calcific tendinitis
 Synovitis
 Fractures
 Bicipital tendinitis
 Cervical radiculopathy (C5, C6)
 Peripheral nerve entrapment (suprascapular)
 Complex regional pain syndrome
 Brachial plexopathies, thoracic outlet syndrome
 Neoplastic conditions
 Rheumatic conditions

Treatment

Initial

The treatment goals depend on the stage of adhesive capsulitis, but the general goals are to decrease pain and inflammation while increasing the shoulder range of motion in all planes [1–3]. Initially, pain and inflammation should be managed with ice, medications, and activity modifications. Reducing inflammation and pain through the use of non-steroidal anti-inflammatory drugs is generally advocated, although it has not been clearly shown to have an impact on the resolution of pain [2]. A short trial of oral steroids has been shown to more rapidly decrease pain compared with placebo, but the benefits are not sustained during long-term follow-up [2,10]. Similarly, intra-articular injection of corticosteroids (with or without lidocaine) has been shown to be helpful during the early stages of adhesive capsulitis compared with placebo, but it does not change long-term outcomes [2].

Rehabilitation

Despite the lack of significant well-conducted clinical trials, the standard of treatment mainly involves physical therapy and home exercises to restore range of motion for the treatment of adhesive capsulitis [1,2,10–12]. The clinician will gauge the need for physical therapy versus a home exercise program and rate of progression of therapy as adhesive capsulitis can take months to years to resolve. Factors affecting the setting and pace of rehabilitation include the severity of the patient's symptoms, physical examination findings, ability to perform the exercises appropriately, and compliance with a home exercise program. Initially, pendulum exercises, overhead stretches, and crossed adduction of the affected arm should be taught to patients while they are in the physician's office once adhesive capsulitis is suspected to prevent further loss of function (Fig. 11.4). Some physicians

will manage the patient through a home exercise program with periodic follow-up visits to review the patient's progress. Others will implement physical therapy early to manage pain, to improve the pain-free range of motion, and to prevent further contraction of the joint capsule. As the patient progresses with physical therapy, a more detailed home exercise program should be implemented on the basis of the patient's understanding of and compliance with the exercises. If the patient shows continued progress with less pain and improved range of motion, exercises should be graduated to strengthening of rotator cuff muscles and periscapular stabilizers. The physician should be cognizant of the cost of prolonged physical therapy and encourage the patient to maintain compliance with a home exercise program. Once symptoms resolve, patients should be encouraged to continue the home exercise program to maintain range of motion and to prevent recurrence of adhesive capsulitis.

Procedures

In the treatment of adhesive capsulitis, procedures are often performed in conjunction with physical therapy sessions and primarily involve pain-alleviating modalities. These procedures may include intra-articular joint injection, suprascapular nerve blocks, and joint capsule hydrodilatation [2,13–15]. As noted before, intra-articular injections can be used to break pain cycles. Several small studies using suprascapular nerve blocks have also reported them to be helpful in breaking pain cycles associated with adhesive capsulitis [13]. Hydrodilatation involves glenohumeral injections with saline or lidocaine to lyse adhesions and to distend the capsule. Unfortunately, more studies are needed to fully understand its efficacy [1,14,15].

Surgery

The decision to perform surgery is based on failure of conservative management or an unacceptable quality of life. Manipulation under anesthesia followed by immediate physical therapy focusing on improvement of range of motion of the glenohumeral joint can be helpful for refractory cases. Studies suggest that it results in short-term and long-term improvement in pain and mobility [1,15,16]. However, larger studies are needed to better understand the full impact on recovery. Finally, arthroscopic lysis of adhesions may be an effective option if all else has failed [17,18].

Potential Disease Complications

Most of the complications associated with adhesive capsulitis are related to pain and range of motion loss. Pain is usually transient but can persist for months as the condition runs its clinical course. The loss of range of motion that is seen in adhesive capsulitis is usually regained, but it has been reported that as many as 15% of patients develop permanent loss of full range of motion. This range of motion loss is often not associated with functional deficits [1–3].

Potential Treatment Complications

Treatment complications from conservative management are rare but can include side effects associated with

nonsteroidal anti-inflammatory drugs and analgesic medications; these include gastrointestinal bleeds, gastritis, toxic hepatitis, and renal failure [19]. Caution should be used in the treatment of patients with congestive heart failure and hypertension because of fluid retention associated with the use of nonsteroidal anti-inflammatory drugs. Patients undergoing physical therapy could experience significant pain from too aggressive therapeutic exercises or manipulation. In patients undergoing suprascapular nerve blocks, care must be taken to prevent intraneural and intravascular injections. There has been one reported case of a patient suffering a pneumothorax during a suprascapular nerve block when a spinal needle was used [20]. A common surgical complication that can occur is a humeral fracture during manipulations under anesthesia.

CHAPTER 12

Biceps Tendinopathy

Brian J. Krabak, MD, MBA, FACS

Synonyms

Biceps tendinosis
Bicipital tendinitis

ICD-9 Codes

726.11 Calcifying tendinitis of shoulder
726.12 Bicipital tenosynovitis

ICD-10 Codes

M75.30 Calcifying tendinitis of shoulder, unspecified
M75.31 Calcifying tendinitis of right shoulder
M75.32 Calcifying tendinitis of left shoulder
M75.20 Bicipital tenosynovitis, unspecified shoulder
M75.21 Bicipital tenosynovitis of right shoulder
M75.22 Bicipital tenosynovitis of left shoulder

Definition

First documented in 1932, the term *biceps tendinitis* was used to describe inflammation, pain, or tenderness in the region of the biceps tendon [1]. More recently, *tendinitis* has been replaced by the term *tendinopathy* to reflect the nature of injury secondary to inflammation of the tendon sheath (-itis) versus degeneration of the tendon (-osis) [2,3]. Both represent overuse injuries to the biceps tendon, which helps prevent superior translation of the humeral head during shoulder abduction and is intimately associated with the labrum [4]. The biceps tendon works in concert with the rest of the shoulder muscles to maintain mobility and function. Injury to or compromise of a single muscle of the dynamic shoulder stabilizers can adversely affect other muscles and impair function of the entire joint.

Primary biceps tendinitis describes isolated inflammation of the tendon as it runs in the intertubercular groove; it typically occurs in the younger athletic populations [4].

The precipitating forces in primary biceps tendinitis are multifactorial, including acute repetitive overuse and secondary impingement due to scapular dyskinesis, unilateral instability, and multidirectional shoulder instability [5]. A flat medial wall or shallow bicipital groove can predispose to subluxation of the long head tendon, increasing risk for inflammation [6]. On the other hand, bicipital tendinosis is typically seen in the older population (i.e., athletes older than 35 years or nonathletes older than 65 years) and more commonly than primary biceps tendinitis [1,5]. Studies have found that up to 95% of patients with bicipital tendinosis have associated rotator cuff disease [7].

Symptoms

Biceps tendinopathy usually is manifested with complaints of anterior shoulder pain that is worse with activities involving elbow flexion [2]. Pain usually localizes to the bicipital groove with occasional radiation to the arm or deltoid region. Often, pain will also occur with prolonged rest and immobility, particularly at night. The throwing athlete often describes pain during the follow-through of a throwing motion and may feel a “snap” if the tendon subluxes in the groove [4]. Attention should be given to onset, duration, and character of the pain. Some individuals present with only complaints of fatigue with shoulder movement. A history of prior trauma, athletic and occupational endeavors, and systemic diseases should be considered in evaluating the shoulder. Patients with accompanying “impingement syndrome” often complain of a “pinching” sensation with overhead activities and a “toothache” sensation in the lateral proximal arm. The pain can be difficult to separate from impingement or rotator cuff syndrome [5].

Physical Examination

The physical examination begins with adequate inspection of the shoulder and neck region. Attention is given to prior scars, structural deformities, posture, and muscle bulk. Determination of the exact location of pain can be helpful for diagnosis. Biceps tendinopathy commonly presents with palpable tenderness over the bicipital groove (Fig. 12.1). Side-to-side comparisons should be made because the tendon is typically slightly tender to direct palpation. Tenderness over the lateral aspect of the shoulder suggests bursitis, tendinopathy, or strain of the deltoid muscle. Caution should be used as the accuracy for palpation of the biceps tendon was 5.3%

FIGURE 12.1 Palpation of the bicipital groove.

in residents and fellows [8]. Motion limitation is not seen in isolated tendinopathies but is often seen in concomitant degenerative joint diseases, impingement syndromes, tendon tears, and adhesive capsulitis. Shoulder range of motion may be limited if the rotator cuff is involved. The findings on neurologic examination should be normal, including sensation and deep tendon reflexes. On occasion, strength is limited by pain or disuse. Assessment of the kinetic chain, including scapular stability and spine stabilization, is important.

Special tests of the shoulder should be performed routinely. The Speed and Yergason tests (Figs. 12.2 and 12.3) are often used to help evaluate for bicipital tendinopathy. Unfortunately, a recent meta-analysis suggests that these tests are not sensitive (Speed test, 50%-63%; Yergason test, 14%-32%) or specific (Speed test, 60%-85%; Yergason test, 70%-89%) for diagnosis of biceps tendinopathy [9]. Impingement tests and supraspinatus tests will help assess for any concurrent rotator cuff tendinopathy. Other maneuvers to assess for instability (anterior apprehension, anterior-posterior load and shift), labral disease (O'Brien test), and acromioclavicular joint arthritis (scarf test) should be performed.

Functional Limitations

Biceps tendinitis may cause patients to limit their activities at home and at work. Limitations may include difficulty with lifting and carrying groceries, garbage bags, and briefcases. Athletics that involve the affected arm, such as swimming, tennis, and throwing sports, may be curtailed. Pain may impair sleep.

Diagnostic Studies

Biceps tendinopathy is generally diagnosed on a clinical basis, but imaging studies are helpful to exclude other pathologic

FIGURE 12.2 Demonstration of the Speed test for bicipital tendinitis. The examiner provides resistance to forward flexion of the shoulder with the elbow in extension and supination of the forearm. Pain is elicited in the intertubercular groove in a positive test result.

FIGURE 12.3 Demonstration of the Yergason test. The examiner provides resistance against supination of the forearm with the elbow flexed at 90 degrees. The test result is considered positive when pain is produced or intensified in the intertubercular groove.

processes. Plain radiographs are usually normal [1]. They can, however, show calcifications in the tendon and degenerative disease of the joint that may predispose to tendinitis. The Fisk view is used in evaluating bicipital tendinopathy to assess the size of the intertubercular groove. This may help determine whether there is a relative risk for development of recurrent subluxation of the tendon, which is seen in individuals with short and narrow margins of the intertubercular groove [10].

Ultrasonography can be extremely helpful and a cost-effective way to evaluate the biceps and rotator cuff tendons. Ultrasound can detect increased fluid in the biceps tendon sheath and evidence of tendinosis. In addition, ultrasound allows dynamic evaluation of the shoulder region to better assess biceps tendon subluxation. Recent research suggests that ultrasound of the shoulder is more accurate in confirming a normal biceps tendon or full-thickness tear but less accurate in the diagnosis of partial-thickness tears [11].

Magnetic resonance imaging can detect partial-thickness tendon tears, examine muscle substance, evaluate soft tissue abnormalities and labral disease (magnetic resonance arthrography), and assess for masses. In biceps tendinitis, increased signal intensity is seen on T2-weighted images [12]. However, this finding is also seen with partial tears of the tendon. Tendinosis is manifested with increased tendon thickness and intermediate signal in the surrounding sheath. Arthroscopy is a useful procedure for the evaluation of intra-articular disease but does not play a role in isolated tendinitis.

Differential Diagnosis

- Rotator cuff tendinitis and tears
- Multidirectional instability
- Biceps brachii rupture
- Acromioclavicular joint sprain
- Glenohumeral or acromioclavicular degenerative joint disease
- Rheumatoid arthritis
- Crystalline arthropathy
- Adhesive capsulitis
- Cervical spondylosis
- Cervical radiculopathy
- Brachial plexopathy
- Peripheral entrapment neuropathy
- Referral from visceral organs
- Diaphragmatic referred pain

Treatment

Initial

The treatment of biceps tendinopathies involves activity modification, anti-inflammatory measures, and heat and cold modalities [2,4]. Overhead activities and lifting are to be avoided initially. Workstation assessment and modification can be helpful for laborers. Evaluation of athletic technique and training adaptations are important in athletes. Nonsteroidal anti-inflammatory drugs can assist with decreasing the pain and inflammation in treating tendinitis but do not play a role in tendinosis. Medications to increase blood flow to the tendon (i.e., nitro patches) may facilitate recovery. Ice is helpful after exercise for minimizing pain [3,4]. Moist heat can be useful before activity. Other modalities, such as iontophoresis and electrical stimulation, have been used, but there are no clinical trials supporting their efficacy.

Rehabilitation

Rehabilitation for biceps tendinopathy is similar to that for rotator cuff tendinopathy (see Chapter 16). Moreover, because biceps tendinitis rarely occurs in isolation, it is

important to rehabilitate the patient by accounting for all of the shoulder disease that is present (e.g., instability, impingement) [1,2]. Shoulder stretching helps maintain or improve range of motion and is emphasized in all important shoulder movements of abduction, adduction, and internal and external rotation. Posterior capsule stretching is also important, particularly when impingement syndrome is also present. Once full, pain-free active range of motion is achieved, progressive resistance exercises are used to strengthen the dynamic shoulder and spine stabilizers, progressing from static to dynamic exercise as tolerated [4]. Eccentric strengthening exercises may be beneficial for biceps tendinopathy, but more research is needed. Overhead and shoulder abduction activities should be avoided early in treatment because they can exacerbate symptoms. Scapular and spine stabilization exercises should be introduced once biceps strength improves. The exercise program should progress to sport-specific functional activities, when appropriate. Athletes may return to play, gradually, when pain is minimal or absent [4].

Procedures

Steroid injections are a potentially useful adjunct for biceps tendinitis (Fig. 12.4) but should probably be avoided in cases

FIGURE 12.4 Injection technique for the long head of the biceps brachii (ideally performed under ultrasound guidance). Under sterile conditions with use of a 25-gauge, 1½-inch disposable needle and a local anesthetic-corticosteroid combination, the area surrounding the biceps tendon is injected. It is important to bathe the tendon sheath in the preparation rather than to inject the tendon itself. Typically, a 1- to 3-mL aliquot of the mixture is used (e.g., 1 mL of 1% lidocaine mixed with 1 mL of betamethasone). (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

of tendinosis. The goal of an injection would be to diminish pain and inflammation while facilitating the rehabilitation treatment program. Injections must be used judiciously to avoid weakening of the tendon substance. Ideally, injections should be performed under ultrasound guidance to improve accuracy and to avoid complications from injecting the tendon [13]. Immediate postinjection care includes icing for 5 to 10 minutes, and the patient may continue to apply ice at home for 15 to 20 minutes, two or three times daily, for several days. The patient should be instructed to avoid heavy lifting or vigorous exercise for 48 to 72 hours after injection. Injection of biologics (autologous blood and platelet-rich plasma) is potentially promising but needs further research to better define its utility [14]. Depending on the concurrent shoulder disease, other injections may also be useful (e.g., subacromial) [15].

Surgery

Surgery is generally not indicated for isolated biceps tendinitis. However, biceps tenodesis in conjunction with acromioplasty in chronic, refractory cases and in those cases associated with rotator cuff impingement has been found to have good results [16]. Tenotomy of the long head of the biceps for chronic tendinitis remains controversial, and long-term results are unknown [16,17].

Potential Disease Complications

Progressive biceps tendinitis and pain can lead to diminished activity, rotator cuff disease, and adhesive capsulitis. Compensatory problems with other tendons can develop because of their interdependence for proper shoulder movement. The development of myofascial pain of the surrounding shoulder girdle muscles is another common complication in shoulder tendinopathy.

Potential Treatment Complications

The exercise program should be properly supervised initially to prevent aggravation of tendinitis of other muscle groups. Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect

the gastric, hepatic, and renal systems. Repeated steroid injections in or near tendons could result in tendon rupture and should be performed under ultrasound guidance, whenever possible.

CHAPTER 13

Biceps Tendon Rupture

Michael F. Stretanski, DO

Synonyms

Biceps brachii rupture
Biceps tear
Bicipital strain

ICD-9 Codes

727.62 Rupture of tendon of biceps (long head), nontraumatic
840.8 Sprain or strain of other specified site of shoulder and upper arm

ICD-10 Codes

M66.821 Rupture of tendon of biceps (upper arm), nontraumatic, right
M66.822 Rupture of tendon of biceps (upper arm), nontraumatic, left
M66.829 Rupture of tendon of bicep (upper arm), nontraumatic, unspecified

Definition

Biceps tendon rupture is either complete or partial disruption of the tendon of the biceps brachii muscle that can occur proximally or distally. The more common proximal ruptures are frequently seen in older individuals who have had chronic tendinosis of the long head of the biceps tendon associated with concomitant rotator cuff disease and degenerative joint disease of the shoulder [1] (Fig. 13.1). The incidence is 1.2 per 100,000 patients, with a majority on the dominant side of men who smoke and are in the fourth decade of life [2]. Most cases involve the long head of the biceps brachii and are manifested as a partial or complete avulsion from the superior rim of the anterior glenoid labrum [3]. Rupture of the proximal biceps tendon represents 90% to 97% of all biceps ruptures; it almost exclusively involves the long head [4] and is 7.5 times more likely in smokers [2].

Recent cadaveric study suggests that the relative avascularity of the long head of the biceps tendon may be a risk

factor, as seen in many other tendon ruptures. Supplied through its osteotendinous and musculotendinous junctions and rarely branches from the anterior circumflex humeral artery traveling in a mesotenon, the long head of the biceps tendon has a hypovascular region in the border of two adjacent vascular territories. This region of limited arterial supply, 1.2 to 3 cm from the tendon origin, extends midway through the glenohumeral joint to the proximal intertubercular groove [5]. The distal biceps rupture is relatively uncommon and typically occurs in middle-aged men, although acute traumatic ruptures may occur in younger individuals or in anyone engaged in predisposing activities, such as forceful explosive contraction of the biceps. Patients with a distal biceps tendon rupture carry a risk of at least 8% for a rupture on the contralateral side [6]. This often develops suddenly with stressing of the flexor mechanism of the elbow. Distal biceps rupture usually occurs as a single traumatic event, such as with heavy lifting; it is often an avulsion of the tendon from the radial tuberosity, but it can also occur as a midsubstance tendon rupture [7].

Symptoms

Proximal ruptures are often asymptomatic and are commonly discovered with awareness of distal migration of the biceps brachii muscle mass, or they may occur suddenly by a seemingly trivial event. Often, individuals will note an acute “popping” sensation. The patient often takes one finger and points directly to the bicipital groove when describing the pain. Edema and ecchymosis may be seen with tendon rupture but also with other regional pathologic processes. The proximal ruptures are typically less painful but can be preceded by chronic shoulder discomfort [8]. An acute distal rupture is often associated with pain at the antecubital fossa that is typically aggravated by resisted elbow flexion. The pain is usually sharp initially but improves with time and is often described as a dull ache [9]. Swelling, distal ecchymosis, and proximal migration of the biceps brachii muscle mass accompany this injury with a magnitude dependent on the degree of injury. Younger, healthy patients may often present with a cosmetic rather than a functional complaint.

Physical Examination

Visual inspection of the biceps brachii, including comparison with the unaffected limb, is usually the first and most

FIGURE 13.1 Proximal biceps tendon rupture.

FIGURE 13.2 The Ludington test is performed by having the patient clasp both hands onto or behind the head, allowing the interlocking fingers to support the arms. This action permits maximum relaxation of the biceps tendon in its resting position. The patient then alternately contracts and relaxes the biceps while the clinician palpates the tendon and muscle. In a complete tear, contraction is not felt on the affected side.

critical element in the physical examination of this condition. Advances in portability, training, and technology have led to a larger trend among physicians in various specialties to integrate diagnostic musculoskeletal ultrasound into the early phases of routine clinical assessment [10].

The Ludington test [11] is a recommended position in which to observe differences in the contour and shape of the biceps (Fig. 13.2). Diagnosis of complete ruptures is relatively easy; patients often come in aware of the biceps muscle retraction. Partial ruptures exist along a spectrum

and can be more difficult to diagnose. The clinician should also assess for the presence of ecchymosis or swelling as a sign of acute injury. Palpation for point tenderness will often reveal pain at the rupture site. An effort should also be made to determine whether the rupture is complete by palpation and observation of the tendon. Thorough assessment of the shoulder and elbow should be made for range of motion and laxity. The Yergason [12] and Speed [13] tests (see Chapter 12), which are used in the assessment of bicipital tendinitis, are also recommended. Posterior dislocation of the long head of the biceps tendon has been reported [14] and may share some common physical examination findings but not muscle retraction.

In patients with inconsistent physical examination findings and questionable secondary gains, the American Shoulder and Elbow Surgeons subjective shoulder scale [15], a standardized scale of shoulder function with patient and physician components, has demonstrated acceptable psychometric performance for outcomes assessment in patients with shoulder instability, rotator cuff disease, and glenohumeral arthritis [16]. It is important to examine the entire shoulder and to keep in mind that it is a complex, inherently unstable, well-innervated joint that tends to function, and fail, as a unit; therefore, additional lesions that are the true pain generator may be evident. One study [17] looking at shoulder magnetic resonance findings showed no statistical relationship between the level of disability and either biceps tendon rupture or biceps tendinopathy; rather, disability was linked to supraspinatus tendon lesions and bursitis.

A thorough neurologic and vascular examination is performed, and findings should be normal in the absence of concomitant problems. Caution should be used with strength testing or end-range motion to avoid worsening of an incomplete tear.

Functional Limitations

The functional limitations are generally relatively minimal with proximal biceps rupture [18], and the patient's concern is often centered around cosmetic considerations. More significant weakness of elbow flexion and supination is noted after a distal tendon disruption. Pain can be acutely limiting after both situations but is typically more of a problem in distal rupture. The primary role of the biceps brachii is supination of the forearm. Elbow flexion is functional by the action of the brachialis and brachioradialis. A degree of residual weakness with supination and elbow flexion, particularly after distal tendon rupture, can cause functional impairment for individuals who perform heavy physical labor [19]. Fatigue with repetitive work is also a common complaint with nonsurgically treated distal tendon ruptures [20]. The long head of the biceps is thought to play a role in anterior stability of the shoulder [21,22]; this is an issue for people who perform overhead activities (such as lifting, filing, and painting), powerlifting (in which the final 10% of strength is crucial), and nonsports activities in which the appearance of symmetry is important (such as modeling or bodybuilding).

Diagnostic Studies

The diagnosis of biceps brachii rupture is often made on a clinical basis alone. Magnetic resonance imaging is helpful

in confirming the diagnosis and assessing the extent of the injury, but it should be performed in the FABS (flexed elbow, abducted shoulder, forearm supinated) position to obtain a true longitudinal view [23]; it is particularly useful in partial ruptures. Magnetic resonance imaging studies can also assess concomitant rotator cuff disease. Diagnostic ultrasound, which has grown in applicability and portability, may have a role in demonstrating not only proximal but also distal biceps tendon bifurcation [24]. Diagnostic ultrasound may be more cost-effective as an initial screening tool when no surgical injuries are suspected. Imaging of the entire insertion site as well as of elbow structures should be performed in distal ruptures [25]. Plain radiographs sometimes show hypertrophic bone formation related to chronic degenerative tendon abnormalities as a predisposition to rupture. Radiographs are also obtained in acute traumatic cases to rule out fractures and to identify developmental variants. Electrodiagnostic medicine consultation for possible peripheral nerve damage should be considered in cases with evidence of lower motor neuron findings or where the distribution of weakness is not fully accounted for by pain. Attention should be paid to median neuropathy at the elbow and, although it is technically difficult, to lateral antebrachial cutaneous nerve studies.

Differential Diagnosis

- Musculocutaneous neuropathy
- Rotator cuff disease
- Brachial plexopathy
- Pectoralis major muscle rupture
- Tumor
- Hematoma
- Dislocated biceps tendon
- Cervical radiculopathy
- Parsonage-Turner syndrome
- Isolated subscapularis tendon disease

Treatment

Initial

For most patients, treatment of proximal biceps tears is conservative. Gentle range of motion exercises for prevention of contractures of the elbow and shoulder (adhesive capsulitis) can be started almost immediately. The function of the long head of the biceps tendon and its role in glenohumeral kinematics presently remain only partially understood because of the difficulty of cadaveric and in vivo biomechanical studies. Most treatment and rehabilitation efforts remain evidence based [26]. Surgery is rarely necessary because there is little loss of function with this tear, and the cosmetic deformity is generally acceptable without surgical repair. Young athletes or heavy laborers may be the exception; they typically need the lost strength that occurs with loss of the continuity of the biceps tendon [27]. Distal tears are more commonly referred to surgery acutely. However, initial treatment of partial distal ruptures consists of splint immobilization in flexion, which should be continued for 3 weeks. This is followed by a gradual return to normal activities. Analgesics, nonsteroidal anti-inflammatory

drugs, topical agents (menthol-based or other custom compounded), therapeutic ultrasound, and ice may assist with the swelling and discomfort and facilitate rehabilitation efforts in both proximal and distal ruptures.

Rehabilitation

Nonsurgical treatment includes gentle range of motion exercises of the elbow and shoulder for contracture prevention. Modalities such as iontophoresis and therapeutic ultrasound can be used for pain control and prevention of contraction. Electrical stimulation is largely contraindicated in a partial tear (because of the concern of converting it to a complete tear) and not indicated in a complete tear. Gentle strengthening can typically be done after the acute phase in complete tears that are not going to be repaired because there is little chance of further injury. Partial ruptures can scar and remain in continuity [2].

Postoperative rehabilitation for distal biceps rupture repairs consists of immobilization of the elbow in 90 degrees of flexion for 7 to 10 days, followed by the use of a hinged flexion-assist splint with a 30-degree extension block for 8 weeks after surgery. Gentle range of motion and progressive resistance exercises are started initially; unlimited activity is not typically allowed until 5 months postoperatively [28].

Procedures

No procedures are performed in the direct treatment of biceps tendon rupture. Musculocutaneous nerve, upper trunk brachial plexus, and maybe even stellate ganglion blocks may have a role either perioperatively or palliatively in selected cases. Suprascapular nerve block or subacromial infiltration of local anesthetic may have a role in facilitation of rehabilitation therapies, including maintenance of range of motion and prevention of a secondary adhesive capsulitis. The author often coordinates such local anesthetic infiltrations just before physical or occupational therapy appointments. Caution should be exercised during passive stretching, and even then only by therapists who are familiar with suppression of protective mechanisms, to avoid further soft tissue damage at what may be atypical and asymmetric end-range motion. There may be a role for steroid injection in professional or elite athletes during critical phases of their season. In such cases, the subacromial approach is preferred with avoidance of direct needle entry into the biceps tendon. Pulsed radiofrequency of the suprascapular nerve may also have a longer term role in palliation of pain and has the advantage of not requiring steroid injection.

Surgery

Prompt assessment is necessary for complete distal biceps ruptures under consideration for surgical repair because muscle shortening will occur over time. The same is true for proximal ruptures in very active individuals who require maximal upper body strength for their vocation or sport. Optimal surgical outcomes are obtained if treatment occurs within the first 4 weeks after injury. Partial distal ruptures are generally observed nonoperatively until a complete rupture occurs. Several techniques, including the two-incision,

buttonhole, and Boyd-Anderson approaches, are used. More recently, a sonographically guided, mini-open technique involving one incision giving access to three peripectoral anatomic zones has been described [29]. The goal of surgical treatment is to restore strength of supination and flexion. For distal repairs, this is typically performed by a two-incision technique involving reinsertion of the biceps tendon to the radial tuberosity [30]. A single-incision technique with use of suture anchors in the bicipital tuberosity has shown excellent long-term functional results by the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire [31].

Potential Disease Complications

Complications from isolated biceps rupture are relatively rare. Partial tears can become complete tears. Attention should be given to potential contracture formation. Median nerve compression has been reported presumably to be related to an enlarged synovial bursa associated with a partial distal biceps tendon rupture [32]. Isolated antebrachial cutaneous neuropathy, due to traction from the biceps tendon displacing the nerve laterally with alleviation of symptoms after proximal biceps tenodesis, has been reported [33]. Compartment syndrome has also been reported in proximal biceps rupture in a patient receiving systemic anticoagulation [34]. The risk-benefit ratio of discontinuing drugs known to have an association with tendon rupture should be ascertained.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Advancement of the extent of the rupture can occur with overly aggressive strengthening measures and passive stretching. The potential for serious surgical complications is most significant with distal rupture because of the important neurovascular structures in that region, including the median and radial nerves and brachial artery and vein [26]. The complication rate increases with the length of time after rupture that surgery is performed. Proximal radial-ulnar synostosis and heterotopic ossification have also been reported as rare postsurgical complications [21], as has humeral fracture after subpectoral biceps tenodesis [35]. Stiffness and contractures are possible with or without surgical intervention.

Definitions

Shoulder instability represents a spectrum of disorders ranging from shoulder subluxation, in which the humeral head partially slips out of the glenoid fossa, to shoulder dislocation, which is a complete displacement of the humeral head out of the glenoid. It is classified as anterior, posterior, or multidirectional and on the basis of its frequency, etiology, direction, and degree. Instability can result from macrotrauma, such as shoulder dislocation, or repetitive microtrauma associated with overhead activity, and it can occur without trauma in individuals with generalized ligamentous laxity [1–4].

The glenohumeral joint has a high degree of mobility at the expense of stability. Static and dynamic restraints combine to maintain the shoulder in place with overhead activity. Muscle action, particularly of the rotator cuff and scapular stabilizers, is important in maintaining joint congruity in midranges of motion. Static stabilizers, such as the glenohumeral ligaments, the joint capsule, and the glenoid labrum, are important for stability in the extremes of motion [2].

Traumatic damage to the shoulder capsule, the glenohumeral ligaments, and the inferior labrum is a result of acute dislocation. Repeated capsular stretch, rotator cuff, and superior labral injuries are associated with overuse injury resulting in anterior instability in athletes who participate in overhead sports; a loose patulous capsule is the primary pathologic change with multidirectional instability, and patients may present with bilateral symptoms [4–6]. Shoulder instability affects, in particular, young individuals, females, and athletes, but it may also affect sedentary individuals, with an incidence of 1.7% in the general population [1,7,8].

Traumatic instability often occurs when the individual usually falls on an outstretched, externally rotated, and abducted arm with a resulting anterior dislocation. A blow to the posterior aspect of the externally rotated and abducted arm can also result in anterior dislocation. Posterior dislocation usually results from a fall on the forward flexed and adducted arm or by a direct blow in the posterior direction when the arm is above the shoulder [5].

Recurrent shoulder instability after a traumatic dislocation is common, particularly when the initial event happens

at a young age. In these individuals, it may occur repeatedly in association with overhead activity, and it may even happen at night, while changing position in bed, in those with severe instability. The patients may initially require visits to the emergency department or reduction of recurrent dislocation by a team physician; but as the condition becomes more chronic, some may be able to reduce their own dislocations [9,10].

Patients with neurologic problems such as stroke, brachial plexus injury, and severe myopathies may develop shoulder girdle muscle weakness, scapular dysfunction, and resultant shoulder instability.

Symptoms

With atraumatic instability or subluxation, it may be difficult to identify an initial precipitating event. Usually, symptoms result from repetitive activity that places great demands on the dynamic and static stabilizers of the glenohumeral joint, leading to increased translation of the humeral head in overhead sports and occupational activities. Pain is the initial symptom, usually associated with impingement of the rotator cuff under the coracoacromial arch. Patients may also report that the shoulder slips out of the joint or that the arm goes “dead,” and they may report weakness associated with overhead activity [1–3,9–11].

Patients with neurologic injury present with pain with motion and shoulder subluxation as well as scapular and shoulder girdle muscle weakness. In the case of a patient with acute shoulder injury, factors to identify include the patient’s age, dexterity or dominant side, sports and position, activity level, mechanism of injury, and any associated symptoms such as neurologic or functional deficits. In cases of acute dislocation, the age at first dislocation is a prognostic indicator in view of a recurrence of 75% to 100%, especially in skeletally immature individuals [11].

Physical Examination

The shoulder is inspected for deformity, atrophy of surrounding muscles, asymmetry, and scapular winging. Individuals are observed from the anterior, lateral, and posterior positions with the shoulder in neutral position on the side of the body as well as with flexion and abduction motion. Palpation of soft tissue and bone is systematically addressed and includes the four joints that compose the shoulder complex (sternoclavicular, acromioclavicular, glenohumeral, and scapulothoracic), rotator cuff, biceps tendon, and subacromial region.

Passive and active range of motion is evaluated. Differences between passive and active motion may be secondary to pain, weakness, or neurologic damage. Repeated throwing may lead to an increase in measured external rotation accompanied by a reduction in internal rotation; tennis players may present with an isolated glenohumeral internal rotation deficit [12]. These changes may be secondary to posterior capsule tightness, humeral torsion, and glenohumeral laxity that may lead to internal impingement [12].

Manual strength testing is performed to identify weakness of specific muscles of the rotator cuff and

FIGURE 14.1 In the lift-off test of the subscapularis, the patient places the arm on the lower back area and attempts to forcefully internally rotate against the examiner’s hand. It is important to document first that the patient has enough passive motion to allow the shoulder to be internally rotated away from the lower back area.

the scapular stabilizers. The supraspinatus muscle can be tested in the scapular plane with internal rotation or external rotation of the shoulder, and the external rotators are tested with the arm at the side of the body. The subscapularis muscle can be tested by the lift-off test, in which the palm of the hand is lifted away from the lower back (Fig. 14.1). The scapular stabilizers, such as the serratus anterior and the rhomboid muscles, can be tested in isolation or by doing wall pushups. Sensory examination of the shoulder girdle is performed to rule out nerve injuries.

Testing the shoulder in the position of 90 degrees of forward flexion with internal rotation (Hawkins maneuver) or in extreme forward flexion (until 180 degrees) with the forearm pronated (Neer maneuver) can assess for rotator cuff impingement and may reproduce symptoms of pain [10] (Fig. 14.2). Glenohumeral translation testing for ligamentous laxity or symptomatic instability should be documented. Apprehension testing can be performed with the patient sitting, standing, or in the supine position. The shoulder is stressed anteriorly in the position of 90 degrees of abduction and external rotation to reproduce the feeling that the shoulder is coming out of the joint (apprehension test). A relocation maneuver that reduces the symptoms of instability also aids in the diagnosis but appears to be less specific than apprehension

FIGURE 14.2 Impingement test for impingement against the coracoacromial arch.

testing [11] (Fig. 14.3). The causation of posterior shoulder pain (rather than symptoms of instability) with apprehension testing may be associated with internal impingement of the rotator cuff and posterior superior labrum [13–19] (Fig. 14.4).

Other tests for shoulder laxity include the load and shift maneuver with the arm at the side to document humeral head translation in anterior and posterior directions and the sulcus sign to document inferior humeral head laxity. Labral injuries can be evaluated with a combination of tests including the active compression test described by O'Brien and colleagues in which a downward force is applied to the forward flexed, adducted, and internally rotated shoulder to reproduce pain associated with superior labral tears or acromioclavicular joint disease. In the crank test, pain and clicking are reproduced when the shoulder is abducted to 160 degrees and an axial load is placed on the humerus and the arm is internally and externally rotated. Another test is the biceps loading test, in which the patient is asked to supinate the forearm, abduct the shoulder to 90 degrees, flex the elbow to 90 degrees, and externally rotate the arm until apprehensive and the examiner provides resistance against elbow flexion. Pain would suggest a proximal biceps tendinopathy or a labral tear [13–19].

Functional Limitations

Impairment includes reduced motion, muscle weakness, and pain that interfere with activities of daily living, such as reaching into cupboards and brushing hair. Athletes, particularly those participating in throwing sports, may experience a decrease in the velocity of their pitches, and tennis players may lose control of their serve.

FIGURE 14.3 A, Apprehension relocation test in supine position with arm in 90 degrees of abduction and maximal external rotation. B, Reduction of symptoms of apprehension with posteriorly directed force on proximal humerus. C, Increased symptoms of apprehension or pain with anterior force applied on proximal humerus.

Occupational limitations may include inability to reach or to lift weight above the level of the head or pain with rotation of the arm in a production line. Recurrent instability often leads to avoidance of activities that require abduction and external rotation because of reproduction of symptoms.

Diagnostic Studies

The standard radiographs that are obtained to evaluate the patient with shoulder symptoms include anteroposterior

FIGURE 14.4 Internal impingement test. The arm is abducted to approximately 90 degrees and progressively externally rotated to reproduce pain in the posterior aspect of the shoulder.

views in external and internal rotation, outlet view, axillary lateral view, and Stryker notch view. These allow an assessment of the greater tuberosity and the shape of the acromion and reveal irregularity of the glenoid or posterior humeral head as well as dysplasia, hypoplasia, or bone loss that can contribute to instability [3,20].

Special tests that can also be ordered include arthrography, computed tomographic arthrography, magnetic resonance imaging, and magnetic resonance arthrography. These should be ordered to look for rotator cuff or labral abnormalities in the patient who has not responded to treatment. Magnetic resonance arthrography allows better evaluation of rotator cuff, glenoid labrum, and glenohumeral ligaments [3,21]. Gadolinium contrast enhancement and modification of the position of the arm for the test appear to increase the sensitivity of magnetic resonance imaging in identifying the specific location of capsular or labral pathologic changes associated with recurrent instability and dislocation [3,21]. Musculoskeletal sonography has grown in popularity in the last decade, and its use in shoulder disease has been well documented. Evaluation of shoulder instability is limited to visualization of the posterior labrum and the rotator cuff tendons and evaluation for paralabral cysts that may suggest labral injury [22]. Diagnostic arthroscopy can be used in some cases but is generally not necessary.

Differential Diagnosis

- Glenohumeral joint instability
 - Post-traumatic
 - Atraumatic
 - Multidirectional
- Rotator cuff tendinitis or tendinosis
- Rotator cuff tear or insufficiency
- Glenoid labral tear
- Suprascapular neuropathy

Treatment

Initial

Acute management of glenohumeral instability is nonoperative in the majority of cases. This includes relative rest, ice, and analgesic or anti-inflammatory medication. Goals at this stage are pain reduction, protection from further injury, and initiation of an early rehabilitation program.

If the injury was observed (as often occurs in athletes) and no neurologic or vascular damage is evident on clinical examination, reduction may be attempted with traction in forward flexion and slight abduction, followed by gentle internal rotation. If this fails, the patient should be transported away from the playing area; reduction may be attempted by placing the patient prone, sedating the individual, and allowing the injured arm to hang from the bed with a 5- to 10-pound weight attached to the wrist. If fracture or posterior dislocation is suspected, the patient should undergo radiologic evaluation before a reduction is attempted. After the reduction, radiologic studies should be repeated [1,3,23–25].

When acute shoulder dislocations are treated nonoperatively, they are usually managed with 1 to 4 weeks of immobilization in a sling, in which the arm is positioned in internal rotation, followed by an exercise program and gradual return to activity. Several studies have suggested that placement of the arm in a position of external rotation may be more appropriate because of better realignment of anatomic structures and reduction position [23–26]. However, this issue still merits further study because there is a lack of randomized controlled studies demonstrating a significant reduction in recurrent dislocation rates or a difference in return to activity levels in comparing the positions of immobilization after reduction or the duration of the postreduction immobilization period [25].

Rehabilitation

The rehabilitation of glenohumeral instability should begin as soon as the injury occurs. The goals of nonsurgical management are reduction of pain, restoration of full functional motion, correction of muscle strength deficits, achievement of muscle balance, and return to full activity free of symptoms. The rehabilitation program consists of acute, recovery, and functional phases [2–4,17–19] (Table 14.1).

Acute Phase (1 to 2 weeks)

This phase should focus on treatment of tissue injury and clinical signs and symptoms. The goal in this stage is to allow tissue healing while reducing pain and inflammation. Reestablishment of nonpainful active range of motion, prevention of shoulder girdle muscle atrophy, reduction of scapular dysfunction, and maintenance of general fitness are addressed.

Recovery Phase (2 to 6 weeks)

This phase focuses on obtaining normal passive and active glenohumeral range of motion, restoring posterior capsule flexibility, improving scapular and rotator cuff muscle strength, and achieving normal core muscle strength and balance. Flexibility training should include the sleeper stretch; strength training includes exercises for the lower

Table 14.1 Glenohumeral Instability Rehabilitation

	Acute Phase	Recovery Phase	Functional Phase
Therapeutic intervention	Active rest Cryotherapy Electrical stimulation Protected motion Isometric and closed chain exercise to shoulder and scapular muscles General conditioning Nonsteroidal anti-inflammatory drugs	Modalities: superficial heat, ultrasound, electrical stimulation Range of motion exercises, flexibility exercises for posterior capsule Scapular control: closed chain exercises, proprioceptive neuromuscular facilitation patterns Dynamic upper extremity strengthening exercise: isolated rotator cuff exercises Sports-specific exercises: surgical tubing, multiplanar joint exercises, core and lower extremity Gradual return to training	Power and endurance in upper extremities: diagonal and multiplanar motions with tubing, light weights, medicine balls, plyometrics Increased multiple-plane neuromuscular control Maintenance: general flexibility training, strengthening, power and endurance exercise program Sports-specific progression
Criteria for advancement	Pain reduction Recovery of pain-free motion Symptom-free progression of muscle strengthening exercises	Full nonpainful motion Normal scapular stabilizers and rotator cuff strength Correction of posterior capsule inflexibility Symptom-free progression in a sports-specific program	Normal clinical examination Normal shoulder mechanics Normal kinematic chain integration Completed sports-specific program Normal throwing motion

FIGURE 14.5 Approximate surface anatomy (*insets*) and internal anatomic sites for injection of the glenohumeral joint laterally and anteriorly. See also [Figure 14.6](#). (From Lennard TA. *Physiatric Procedures*. Philadelphia, Hanley & Belfus, 1995.)

FIGURE 14.6 Posterior injection of the glenohumeral joint. (From Lennard TA. *Physiatric Procedures*. Philadelphia, Hanley & Belfus, 1995.)

trapezius and serratus anterior muscle. This phase can be started as soon as pain is controlled and the patient can participate in an exercise program without exacerbation of symptoms. Young individuals with symptomatic instability need to progress slowly to the position of shoulder abduction and external rotation. Athletes can progress rapidly through the program and emphasize exercises in functional ranges of motion. Older patients with goals of returning to activities of daily living may require slower progression, particularly if they have significant pain, muscle inhibition, and weakness. Biomechanical and functional deficits including abnormalities in the throwing motion should also be addressed.

Functional Phase (6 weeks to 6 months)

This phase focuses on increasing power and endurance of the upper extremities while improving neuromuscular control because a normal sensorimotor system is key in returning to optimal shoulder function [24]. Rehabilitation at this stage works on the entire kinematic chain to address specific functional deficits.

After the completion of rehabilitation, a continued exercise program with goals of preventing recurrent injury should be instituted for individuals who participate in sports, recreational activities, or work-related tasks in which high demands on the shoulder joint are expected. A training program that combines flexibility and strengthening exercises with neuromuscular as well as proprioceptive training should be ongoing. Patients with multidirectional instability need to work specifically on strengthening of the scapular stabilizers and balancing the force couples between the rotator cuff and the deltoid muscle.

Procedures

If the individual persists with some symptoms of pain secondary to rotator cuff irritation despite an appropriate rehabilitation program, a subacromial injection could be considered ([Figs. 14.5](#) and [14.6](#)). The patient at that

time should be reevaluated for identification of residual functional and biomechanical deficits that need to be addressed in combination with the injection. Under sterile conditions, with use of a 23- to 25-gauge, 1½-inch disposable needle, inject an anesthetic-corticosteroid preparation by an anterior, posterior, or lateral approach with or without sonographic guidance, based on availability and clinician expertise. Typically, 3 to 8 mL is injected (e.g., 4 mL of 1% lidocaine and 2 mL of 40 mg/mL triamcinolone). Alternatively, the lidocaine may be injected first, followed by the corticosteroid. Postinjection care includes local ice for 5 to 10 minutes. The patient is instructed to ice the shoulder for 15 to 20 minutes three or four times daily for the next few days and to avoid aggressive overhead activities for the following week. Other procedures, such as prolotherapy, platelet-rich plasma injections, and ultrasound-guided infiltrations, are becoming more popular, especially in athletes for other musculoskeletal injuries, but the results of use for shoulder instability are still unknown [27].

Surgery

Because of high rates of recurrent instability after conservative treatment in the active athletic population and, in particular, throwers, early surgical intervention is gaining acceptance [28]. Open repair of Bankart lesions has been the standard surgical intervention after traumatic instability, and it is still reported by some authors as the preferred method because of predictable results in regard to recurrence of dislocation and return to activity [28]. Early arthroscopic repair of the inferior labral defect associated with acute shoulder dislocation is becoming widespread because of an apparent reduction in postoperative morbidity that may allow the athlete an early return to function [29–31].

In the individual with recurrent instability, surgical treatment may need to address abnormalities in the shoulder capsule, glenoid labrum, and rotator cuff. Arthroscopic interventions result in comparable outcomes when they are measured against open surgery, but no “gold standard” method has been established [3]. Surgical interventions include capsular procedures, such as the capsular shift, and labral as well as rotator cuff procedures, such as débridement and repair [32,33]. In many instances, these procedures need to be combined for optimal results in the patient, followed by an accelerated rehabilitation program with guidelines similar to those for the patient treated nonoperatively [34]. Rehabilitation protocols are similar for open and arthroscopic techniques. The shoulder is immobilized with an abduction pillow for 4 to 6 weeks, with therapy initiated if stiffness develops. After immobilization, strengthening exercises (similar to nonsurgical protocols) are recommended. If the rehabilitation protocol is successfully completed, the patient is allowed to return to full activity 4 to 6 months after surgery [3,34,35].

Potential Disease Complications

Complications include recurrent instability with overhead activity, pain in the shoulder region, nerve damage, and weakness of the rotator cuff and scapular muscles. These tend to occur more commonly in patients with multidirectional atraumatic instability. Loss of function may include

inability to lift overhead and loss of throwing velocity and accuracy. Recurrent episodes of instability in the older individual may also be related to the development of rotator cuff tears [36].

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, cardiovascular, and renal systems. Complications of treatment include loss of motion, failure of surgical repair with recurrent instability, and inability to return to previous level of function. Failure of conservative treatment may be associated with incomplete rehabilitation or poor technique. Recurrent dislocation after surgical treatment can be related to not addressing all the sites of pathologic change at the time of the operation [35].

Definition

The glenoid labrum is a densely fibrous tissue that is located along the periphery of the glenoid bone [1] (Fig. 15.1). As the outer labrum transitions from the periphery to its articulation with the glenoid, the histology changes from fibrous to a small fibrocartilaginous zone at the junction with the glenoid [2]. The labrum increases the height and width of the glenoid while also giving extra depth to the joint. This provides increased stability while still allowing great range of motion [3]. The labrum also serves as an attachment point for the long head of the biceps tendon, the glenohumeral ligaments, and the long head of the triceps tendon, forming a periarticular system of fibers that gives the shoulder joint much needed stability [4]. The vascular supply to the labrum is from the posterior humeral circumflex artery, the circumflex scapular branch of the subscapular artery, and the suprascapular artery. These arteries come from the periphery of the labrum, making the articular margins of the labrum avascular [2]. It has also been shown that the superior labrum has less vascular supply than the inferior labrum. The long head of the biceps has a variable attachment to the labrum and glenoid. Approximately 40% to 60% of the biceps tendon originates from the supraglenoid tubercle, and the remaining fibers insert into the labrum [1]. The biceps insertion into the labrum is variable but most commonly is in a more posterior position.

Tears can occur in all regions of the labrum. The most studied injury to the labrum is the superior labral anterior-posterior (SLAP) tear. Anterior dislocations of the shoulder can be associated with a disruption of the anteroinferior labrum and anterior band of the inferior glenohumeral ligament, also known as a Bankart lesion. Posterior shoulder instability may result in injury to the posterior band of the inferior glenohumeral ligament as well as the posterior labrum, or a reverse Bankart lesion. Tears can extend to involve multiple regions of the labrum and have other associated injuries. The SLAP tear and Bankart lesion are the most common and for that reason are the focus of this discussion.

The most common mechanisms for SLAP tears are forced traction on the shoulder and direct compression. Direct compression can occur in the acute traumatic setting or in the chronic setting typical in the overhead throwing athlete. Overhead throwers are predisposed to SLAP

FIGURE 15.1 Normal anatomy of the shoulder.

tears secondary to their adaptive anatomy. They tend to have posterior capsular contractures, loose anterior capsular structures, and a retroverted humeral head, all increasing the amount of external rotation in the shoulder. As a result of these anatomic changes, the arm goes into an extreme externally rotated position while the biceps kinks at its insertion and assumes a more vertical and posterior position. This applies a torsional force to the biceps-labral complex superiorly, resulting in a peel back mechanism on the superior labrum [5,6]. Alternatively, as throwers externally rotate in the cocking phase, the rotator cuff may impinge on the posterior-superior glenoid, causing an “internal impingement” and tearing of the labrum [7].

Snyder [8] classified SLAP tears into four types, which was further modified by Morgan and Maffet. Most physicians think that the four-class system (Fig. 15.2) is sufficient and that the additional classifications could be placed within these basic types, so it is the preferred classification.

Bankart lesions are created by episodes of anterior instability. As the humeral head moves out anteriorly and inferiorly, anterior damage can occur to the anterior-inferior labrum, glenohumeral ligaments, joint capsule, rotator cuff, and possibly neurovascular structures. It has been shown that the Bankart lesion is created about 85% to 97% of the time in anterior dislocations [9,10]. This pathologic change is thought to be an important reason for recurrent instability.

In addition to the labrum's increasing the depth and diameter of the glenoid, the labrum and capsule also create a negative pressure that provides stability through the glenohumeral articulation. If the labrum or capsule is injured, such as in the Bankart lesion, this suction is lost, and this decreases the stability of the shoulder. Several factors may predispose patients to recurrent instability. These include fracture on the glenoid or humeral head, hyperlaxity syndromes, male gender, younger age at initial dislocation, participation in contact or overhead throwing sport, and positive correlation between number of dislocations and risk of future dislocation. Dislocations later in life increase the risk of rotator cuff injury, with tears occurring in nearly 30% of patients older than 40 years and in up to 80% of patients older than 60 years.

FIGURE 15.2 SLAP tear classification. Type I: degenerative tear of the undersurface of the superior labrum with the biceps anchor intact. Type II: tear of the superior labrum as well as of the biceps anchor. Type III: bucket-handle tear of the superior labrum with biceps anchor intact. Type IV: bucket-handle tear of the superior labrum with extension into biceps tendon.

Symptoms

SLAP Tear

A patient with a SLAP tear will most commonly present with symptoms of deep-seated pain, which can be sharp or dull [11]. It is usually located deep within the center of the shoulder and can be made worse with overhead activities,

pushing heavy objects, lifting, or reaching behind the back. Patients may have mechanical symptoms, such as catching, popping, or grinding with rotation of the shoulder. Many patients with a SLAP tear will also have other shoulder disease, making clinical diagnosis challenging [11].

It is essential to obtain a thorough history for trauma to evaluate for traction or compression type injuries, dislocations, and sports (e.g., baseball, football, waterskiing, tennis) they play that may predispose them to this injury. Overhead throwing athletes may suffer decreased velocity and usually complain of pain in the late cocking and early acceleration phase of throwing. They may have weakness due to pain or secondary to a paralabral cyst compressing the suprascapular nerve. Compression on the nerve at the spinoglenoid notch can cause weakness in external rotation as well as deep posterior shoulder pain.

Bankart Lesion

Symptoms of anterior instability are usually obvious as the patient states that there has been a dislocation and continues to complain of pain and instability in that shoulder. Sometimes there is not a history of overt dislocation, but instead the patient has multiple episodes of instability without a complete dislocation. The patient will complain of pain and feeling of impending dislocation with the arm in abduction and external rotation. Important historical variables include the patient's age at first dislocation, need for formal reduction, number of recurrent instability episodes, voluntary instability, and anticipated future sports activities.

The most comfortable position for these patients is usually with the arm in adduction and internal rotation. They avoid abduction and external rotation because this is the position that led to the dislocation and it also stresses the injured labrum, inferior glenohumeral ligament, and subscapularis tendon.

Physical Examination

SLAP Tear

Several clinical tests are designed to assist the clinician in making the SLAP tear diagnosis [12–15]. These tests are trying to do one of two things: to pinch the torn labrum between the humeral head and the glenoid, causing pain or mechanical symptoms, or to place traction on the biceps tendon (Table 15.1). The tests have had variable ranges of sensitivity and specificity between studies, and thus no single test is considered diagnostic. The most commonly performed test is the O'Brien active compression test. This has been shown to be very sensitive but has extremely poor specificity. Accurate diagnosis requires a careful history to correlate with the examination findings.

In many cases, concomitant disease may cloud the physical examination findings [11]. On inspection of the shoulder, there may be atrophy of the supraspinatus and infraspinatus muscles. The supraspinatus atrophy is difficult to observe because of the overlying trapezius muscle. The atrophy can occur because of a paralabral cyst that compresses the suprascapular nerve, or it could be secondary to an associated rotator cuff tear. Palpation of the biceps tendon may demonstrate tenderness within the bicipital groove. The range of motion of the shoulder should be preserved, although throwing athletes may have increased external rotation and loss of internal rotation with a resulting glenohumeral internal rotation deficit [5,6].

Bankart Lesion

Evaluation for anterior instability may include a number of tests (Table 15.2). After reduction of a dislocation, a thorough neurovascular examination should be performed to rule out major vessel or brachial plexus injury. In a typical Bankart lesion with anterior instability, patients will often experience apprehension when the arm is brought

Table 15.1 Common Tests for Diagnosis of SLAP Tears

Test	Instruction	Indication of Positive Test Result
Active compression (O'Brien) test	Arm is forward flexed to 90 degrees, adducted across the body Patient resists downward force on arm in pronated and supinated position of the forearm	Pain is increased in pronated position
Crank test	Arm is abducted >100 degrees in the scapular plane; elbow is flexed to 90 degrees Axial force is applied through the humerus onto the glenohumeral joint and the shoulder is rotated (internal and external rotation)	Pain, catching, clicking
Pain provocative test	Patient abducts shoulder to 90 degrees, flexes elbow to 90 degrees, and pronates and supinates the hand	Pain is worse or present only in pronation
Biceps load test	Patient is supine; shoulder is abducted to 90 degrees; elbow is flexed to 90 degrees The shoulder is externally rotated to a point at which the patient feels pain, apprehension, or maximum external rotation; the patient then performs resisted flexion of the elbow	Worsening of pain when resisted elbow flexion is performed
Compression-rotation test	Patient is supine; shoulder is abducted to 90 degrees; elbow is flexed to 90 degrees Axial load is placed on the glenohumeral joint and the humerus is rotated	Pain, catching, clicking, snapping
Anterior slide test	Patient is sitting and places hands on the hips with thumbs facing posterior The examiner places a finger over the anterior shoulder and the other hand pushes up on the humerus superior and anterior; patient is asked to resist	Pain or click

Table 15.2 Common Tests for Diagnosis of Anterior Instability

Test	Instruction	Indication of Positive Test Result
Load and shift	Supine position Arm at 0, 45, 90 degrees of abduction Anterior directed force on the humerus	Increasing translation at higher degrees of abduction indicates that the inferior glenohumeral ligament is compromised. Grade 1: increased translation compared with contralateral Grade 2: humeral head translates to the glenoid rim Grade 3: translates over the glenoid rim
Apprehension test (crank)	Supine position Arm brought into 90 degrees of abduction and increasing external rotation	Pain, feeling of impending dislocation, or muscle guarding
Relocation (Jobe) test	Apprehension position with posteriorly directed force on the humeral head	Decreased apprehension or pain
Surprise test	Relocation test with sudden release of posteriorly directed force	Sense of instability or apprehension with release of force

into abduction and external rotation. Strength should be assessed, looking for axillary or radial nerve palsies as well as rotator cuff disease in the older patient. In a patient older than 40 years who cannot lift the arm after a dislocation, rotator cuff tear is far more common than an axillary nerve palsy [16,17]. The surprise test has been shown to be the most accurate test, with a positive predictive value of 98% and a negative predictive value of 78% [18].

Functional Limitations

SLAP Tear

Patients may have difficulty carrying or pushing heavy objects, working overhead, and throwing [1]. This pathologic process can often be asymptomatic at rest and symptomatic only with more vigorous activity. SLAP tears often are manifested with a multitude of other shoulder diseases, so limitations may vary according to what else is present in the shoulder along with the SLAP tear [11].

Bankart Lesion

Avoidance of the abducted and externally rotated position is required to limit recurrent instability. This may limit many athletic activities, particularly in contact sports and in throwers.

Diagnostic Studies

SLAP Tear

The initial imaging study for any shoulder pain is plain radiography, including anterior-posterior, scapular anterior-posterior, axillary, and outlet views. There are no typical findings for SLAP tears on radiography, but it is necessary to rule out other sources of pain.

Magnetic resonance imaging (MRI) should be the next test obtained for patients with a high clinical likelihood of labral disease. There is controversy as to whether high-resolution non-contrast-enhanced MRI or magnetic resonance arthrography is the “gold standard” for diagnosis of SLAP lesions [19,20]. With the high rate of concomitant shoulder injuries, MRI is helpful in showing both intra-articular and extra-articular pathologic changes within the

soft tissues. Positioning of the arm in external rotation or abduction and external rotation can improve the ability to accurately diagnose these lesions [21,22]. Computed tomographic arthrography may also be used if MRI is contraindicated, but it is less sensitive to other soft tissue disease. Ultrasound may be useful to visualize concomitant disease, such as tears of the rotator cuff and paralabral cyst, but it has poor visualization of the labrum.

Arthroscopy has been the gold standard for diagnosis of labral disease. Many times the diagnosis is made during arthroscopy after other modalities have failed to make a conclusive diagnosis.

Bankart Lesion

Plain radiography should be performed to rule out dislocation in the acute setting. With more chronic instability, additional views could be considered. The West Point view can assist with visualization of the glenoid in an attempt to see bone disruptions of the glenoid rim; a Stryker notch view may better visualize an associated Hill-Sachs lesion of the humeral head.

In patients with soft tissue Bankart lesions, the radiographs may be unrevealing. MRI would be the next imaging study conducted (Fig. 15.3). In the acute setting,

FIGURE 15.3 Axial magnetic resonance image of a Bankart lesion.

non-contrast-enhanced MRI is reasonable as the hemarthrosis from the dislocation aids in visualization of the labral process. In the chronic setting, magnetic resonance arthrography can improve labral imaging.

Differential Diagnosis

- Impingement syndrome
- Rotator cuff disease
- Acromioclavicular joint disease
- Cervical disc injury
- Cervical radiculopathy
- Brachial plexus injury
- Refractory bicipital tendinitis
- Multidirectional instability
- Bony Bankart lesion
- Humeral avulsion of the glenohumeral ligament
- Malingering

Treatment

Initial

SLAP Tear

Overhead throwing athletes with more than 35 degrees of glenohumeral internal rotation deficit have a 60% chance of shoulder injury that requires them to miss games [5]. Regular posterior-inferior capsular stretching exercises significantly decrease the rate of shoulder injuries in overhead throwing athletes [5,6] and are now a part of preventive care for baseball players.

Initial treatment of a SLAP tear is symptomatic. Nonsteroidal anti-inflammatory medications, cryotherapy, and activity modification are the mainstays of treatment until the acute inflammation and pain subside. A short period of sling immobilization for comfort should be followed by early institution of range of motion exercises.

Bankart Lesion

The Bankart lesion is a result of anterior shoulder instability or dislocation. If the shoulder is dislocated, the initial step in treatment is to reduce the shoulder. Postreduction radiographs should be obtained and neurovascular status checked. Sling immobilization should be instituted for a short period. Recommendations for the duration of immobilization vary from days to weeks. The position of immobilization is controversial as immobilization in external rotation has been shown by some to lower the recurrence rate of instability, but it must be instituted immediately after the instability episode [23,24]. The most common recommendation is for standard sling immobilization for a period of 1 to 3 weeks.

Rehabilitation

SLAP Tear

When a SLAP tear is suspected, the recommended physical therapy focuses on strengthening the rotator cuff, capsular stretching, range of motion of the glenohumeral joint, and scapular stabilization exercises. A study by Edwards showed good results with nonoperative treatment of SLAP tears [25]; 51% of the patients in the study ended up having

surgery, but the remainder reported significant pain relief, 100% returned to sports, and 70% returned to preinjury level. Patients in this study were treated with nonsteroidal anti-inflammatory drugs, scapular strengthening, and posterior capsular stretching. The results are comparable to surgical outcomes, so conservative management should be the first-line treatment.

Postoperative rehabilitation after arthroscopic labral repair involves a 4- to 6-week period of sling immobilization followed by a progressive range of motion and strengthening program. For overhead athletes, a throwing program can begin at 4 months with full return at approximately 7 to 12 months.

Bankart Lesion

After a period of sling immobilization in the acute setting, the patient is progressed through simple passive, active-assisted, and then active range of motion. Once the patient is comfortable with these exercises, the focus shifts to progressive resistance training of the rotator cuff, deltoid, and scapular stabilizers. This should continue until strength and motion are equal bilaterally. The goal is to strengthen the dynamic stabilizers of the glenohumeral joint. Activity modification should be a part of rehabilitation in some patients as well. Avoidance of the activity that led to the dislocation is often reasonable in the older patient but challenging for the young athlete who would like to return to sport. In the young athlete with first-time dislocation, surgical management is becoming more common as nonoperative treatment is not nearly as successful as in the older patient population (older than 30 years). Other nonsurgical options in addition to physical therapy that can be considered in the patient with anterior instability and a Bankart lesion are bracing and taping. Whereas these modalities are directed at preventing the position of abduction and external rotation or preventing humeral subluxation, neither has been shown to decrease the rate of instability.

Procedures

Patients with labral tears can undergo an intra-articular injection with corticosteroid and local anesthetic to help with pain and inflammation. Intra-articular injection should be done in conjunction with the physical therapy as described. This can be done under fluoroscopic or ultrasound guidance or by anatomic landmarks.

Aspiration of paralabral cysts causing compression on the suprascapular nerve can be performed with image guidance. This has been shown to provide relief in 60% of patients, although it is usually temporary. Failure to address the primary pathologic process of the labral tear may allow recurrence of the cyst.

Surgery

SLAP Tear

Surgery is indicated once the patient and physician have decided that nonoperative measures have not been adequate. It is generally recommended that patients have a trial of conservative therapy, usually involving at least a 3-month period of physical therapy and medications, before

proceeding to the operating room. The following surgical procedures are based on the type of injury:

Type I: Gentle débridement of labrum back to stable tissue.

Type II: Arthroscopic labral repair with suture anchors.

Type III: Arthroscopic débridement of the bucket-handle fragment with repair of any unstable portions of the labral rim.

Type IV: Treatment of the biceps disease with débridement, tenotomy, or tenodesis combined with labral repair or débridement.

Patients older than 40 years have had less successful results of superior labral repairs compared with younger patients because pain may continue to be generated by the biceps-labral complex. In this age group, the trend for surgical treatment has been to perform biceps tenodesis with labral débridement.

Treatment of a SLAP tear with associated paralabral cyst involves arthroscopic labral repair with or without cyst decompression. Studies show acceptable outcomes with both approaches.

Bankart Lesion

Labral repair with plication of the attenuated capsule is successful in restoring stability (Fig. 15.4). Modern arthroscopic techniques allow suture anchor fixation of the labrum and capsular plication and have shown success rates comparable to those of traditional open surgery.

Outcomes

SLAP Tear

As discussed in the section on rehabilitation, the literature on nonoperative treatment of SLAP tears is sparse. Edwards and colleagues showed that about 51% of patients treated nonoperatively went on to have an operation. Of those who continued with nonoperative treatment, all returned to sports and about 70% to preinjury level [25].

With simple débridement, the patient usually is provided with good pain relief in the short term. About 80% of patients have good relief for the first year or so, but at 2 years or more, this number decreases to near 60% [26,27]. Type II SLAP tears are the most commonly encountered, so they are the most studied. Many studies report that 90% return to sport and approximately 70% to 80% return to preinjury level.

FIGURE 15.4 Suture anchor repair of Bankart lesion.

Bankart Lesion

Success of nonoperative management is dependent on multiple factors, particularly the age of the patient at first dislocation, athletic activities, associated disease, number of dislocations, and gender. In first-time dislocators older than 30 years, the chance of recurrence is approximately 27%, whereas the patient younger than 30 years has between a 40% and 90% chance of redislocation [28]. Men typically have a higher rate of recurrence than women, as do athletes involved in throwing or contact sports. An associated pathologic process, such as a bony Bankart lesion, large Hill-Sachs lesion, or rotator cuff tear or avulsion, is also predictive of failure of nonoperative treatment.

With open or arthroscopic surgical stabilization, the risk of recurrence compared with conservative treatment is about one fifth that of the nonoperative group [29].

Potential Disease Complications

SLAP tears result in a decrease in overall shoulder stability as the glenoid labrum is disrupted. This is usually well tolerated but can lead to episodes of instability and further damage of the labrum, biceps, capsule, and surrounding ligamentous structures. No data exist to suggest that nonoperative management of SLAP tears leads to significant degenerative changes.

Bankart lesions are caused by shoulder instability, and the pathologic change that they create increases the chance for further instability. This will create greater attenuation and damage to the tissues around and within the shoulder capsule, which can then cause fracture of the glenoid or the humeral head, possible neurovascular compromise, and increased risk of future glenohumeral arthritis.

Potential Treatment Complications

The risk of taking long-term nonsteroidal anti-inflammatory medication includes damage of the gastric and renal systems. Cyclooxygenase 2 inhibitors avoid some of the gastric complications, but there is a concern for cardiovascular complications, and past medical history should be taken into account. Injection of the glenohumeral joint has a small chance of causing septic arthritis.

Nonoperative management of SLAP tears has little risk as conservative management has not been shown to place the shoulder at risk for future deterioration. In the setting of a Bankart tear with anterior instability, recurrent instability episodes do risk further labral, capsular, articular cartilage, and rotator cuff damage. In the younger patient at risk for recurrent instability, this may prompt earlier surgical treatment.

Potential surgical complications specific to labral repairs include postoperative stiffness, recurrent tearing and instability, and post-traumatic arthritis.

CHAPTER 16

Rotator Cuff Tendinopathy

Jay E. Bowen, DO
Gerard A. Malanga, MD

Synonyms

Impingement syndrome
Rotator cuff tendinosis

ICD-9 Code

726.10 Rotator cuff syndrome

ICD-10 Codes

M75.100 Unspecified rotator cuff tear or rupture of unspecified shoulder, not specified as traumatic
M75.101 Unspecified rotator cuff tear or rupture of right shoulder, not specified as traumatic
M75.102 Unspecified rotator cuff tear or rupture of left shoulder, not specified as traumatic
M75.80 Other shoulder lesions, unspecified shoulder
M75.81 Other shoulder lesions, right shoulder
M75.82 Other shoulder lesions, left shoulder

Definition

Rotator cuff tendinopathy is a common phenomenon affecting both athletes and nonathletes. The muscles that compose the rotator cuff—supraspinatus, infraspinatus, subscapularis, and teres minor—may become inflamed or impinged by the acromion, coracoacromial ligament, acromioclavicular joint, and coracoid process [1]. Fibroblastic hyperplasia (tendinosis) may play a role as well. The supraspinatus tendon is the most commonly involved.

Rotator cuff tendinopathy may result from a variety of factors. The tendon or its musculotendinous junction can

be “squeezed” along its course from a relatively narrowed space [2]. Tendinosis can be a result of degeneration from the aging process or from underlying subtle instability of the humeral head [3,4].

In chronic rotator cuff tendinopathy, the muscles of the rotator cuff and surrounding scapulothoracic stabilizers may become weak by disuse. Under these conditions, the muscles can fatigue early, resulting in altered biomechanics. The humeral head moves excessively off the center of the glenoid, usually superiorly [5-8]. From this abnormal motion, impingement of the rotator cuff occurs, causing inflammation of the tendon. This is what many refer to as impingement syndrome; it particularly occurs during forward flexion when the anterior portion of the acromion impinges on the supraspinatus tendon.

With the passage of time, modifications of the acromion occur, resulting in osteophyte formation or “hooking” of the acromion (Fig. 16.1) [1,9]. With repeated superior migration and acromial changes, degeneration of the musculotendinous junction can lead to tearing of the rotator cuff (see Chapter 17). With prolonged shoulder pain, adhesive capsulitis can develop from the lack of active motion (see Chapter 11).

Symptoms

Patients normally present with pain in the posterolateral shoulder region and, often, deltoid muscle pain, which is referred from the shoulder. The pain is described as dull and achy and often occurs at night. Complaints occur with activities above the shoulder level, usually when the arm is abducted more than 90 degrees. Pain is also noted in movements involving eccentric contractions, when sleeping on the affected side, and during overhead activities such as swimming and painting [10-14].

Physical Examination

The shoulder examination is approached systematically in every patient. It includes inspection, palpation, range of motion, muscle strength testing, and performance of special tests of the shoulder as clinically indicated.

The examination begins with observation of the patient during the history portion of the evaluation. The shoulder

FIGURE 16.1 Types of acromial shape (lateral view).

should be carefully inspected from the anterior, lateral, and posterior positions. Because shoulder pain is usually unilateral, comparison with the contralateral shoulder is often useful. Atrophy of the supraspinatus and infraspinatus muscles can be seen in massive rotator cuff tears as well as in entrapments of the suprascapular nerve. Scapular winging is rare in rotator cuff injuries; however, abnormalities of scapulohumeral motion are often present and should be addressed as part of the treatment plan.

Tenderness is often localized to the greater tuberosity, subacromial bursa, or long head of the biceps.

Total active and passive range of motion in all planes and scapulohumeral rhythm should be evaluated. Maximal total elevation occurs in the plane of the scapula, which lies approximately 30 degrees forward of the coronal plane. Patients with rotator cuff tears tend to have altered scapulohumeral motion during active shoulder elevation. Decreased active elevation with normal passive range of motion is usually seen in rotator cuff tears secondary to pain and weakness. When both active and passive range of motion is similarly decreased, this usually suggests the onset of adhesive capsulitis. Glenohumeral internal rotation is assessed most accurately by abduction of the shoulder to 90 degrees and manual fixation of the scapula. From this point, the elbow is flexed to 90 degrees and the humerus is internally rotated. The impingement syndrome associated with rotator cuff injuries tends to cause pain with elevation between 60 and 120 degrees (painful arc), when the rotator cuff tendons are compressed against the anterior acromion and coracoacromial ligament [5,6,15].

Muscle strength testing should be done isolating the relevant individual muscles. The anterior cuff (subscapularis) can be assessed by the lift-off test (see Chapter 14, Fig. 14.1), which is performed with the arm internally rotated behind the back. Lifting of the hand away from the back against resistance tests the strength of the subscapularis muscle. The posterior cuff (infraspinatus and teres minor) can be tested with the arm at the side and the elbow flexed to 90 degrees. Significant weakness in external rotation will be seen in large tears of the rotator cuff. The supraspinatus muscle is specifically tested by abduction of the patient's arm to 90 degrees, horizontal adduction to 20 to 30 degrees, and internal rotation of the arm to the thumbs down position. Testing of the scapula rotators, the trapezius, and the serratus anterior is also important. The serratus anterior can be tested by having the patient lean against a wall; winging of the scapula as the patient pushes against the wall indicates weakness [15,16].

Drop Arm Test

The clinician abducts the patient's shoulder to 90 degrees and then asks the patient to slowly lower the arm to the side in the same arc of movement. The test result is positive if the patient is unable to return the arm to the side slowly or has severe pain when attempting to do so. A positive result indicates a tear of the rotator cuff [17].

Impingement Sign

The shoulder is forcibly forward flexed with the humerus internally rotated, causing a jamming of the greater tuberosity against the anterior inferior surface of the acromion. Pain with this maneuver reflects a positive test result and indicates an overuse injury to the supraspinatus muscle and possibly to the biceps tendon (see Chapter 14, Fig. 14.2) [18].

Apprehension Test

The arm is abducted 90 degrees and then fully externally rotated while an anteriorly directed force is placed on the posterior humeral head from behind. The patient will become apprehensive and resist further motion if chronic anterior instability is present (see Chapter 14, Fig. 14.4) [1].

Relocation Test

Perform the apprehension test with the patient supine and the shoulder at the edge of the table (Fig. 16.2). A posteriorly directed force on the proximal humerus will cause resolution of the patient's symptoms of apprehension, which is another indicator of anterior instability (see Chapter 14, Fig. 14.3) [1].

Functional Limitations

Patients with rotator cuff tendinopathy complain of limitations in the performance of overhead activities, such as throwing a baseball and painting a ceiling, particularly above 90 degrees of abduction [19-21]. Pain may also occur with internal and external rotation and may affect daily self-care activities. Women typically have difficulty hooking the bra in back. Work activities, such as filing, hammering overhead, and lifting, can be affected [22,23]. The patient can be awoken by pain in the shoulder, which impairs sleep [12].

Diagnostic Studies

In the event of trauma to the shoulder and complaints consistent with rotator cuff tendinopathy, the clinician should obtain radiographs to avoid missing an occult fracture. The anteroposterior view with internal and external rotation is sufficient for screening. If dislocation is suspected, further views should be obtained, including West Point axillary, true anteroposterior, and Y views.

Magnetic resonance imaging is the study of choice when a patient is not progressing with conservative management or to rule out an alternative pathologic process (e.g., rotator cuff tear). In tendinopathy, magnetic resonance imaging will demonstrate an increased T2-weighted signal within the substance of the tendon [22]. Diagnostic arthroscopy is used in some cases but is generally not necessary.

FIGURE 16.2 Relocation test. **A**, In certain shoulders, pain limits abduction and maximum external rotation. **B**, By the application of pressure on the anterior shoulder, the discomfort is eliminated and greater external rotation is noted.

Electrodiagnostic studies can be ordered to exclude alternative diagnoses as well (e.g., cervical radiculopathy) [15,24].

Subacromial anesthetic injections (see Chapter 14, Figs. 14.5 and 14.6) have been discussed as diagnostic tools to assist in the confirmation of rotator cuff tendinopathy. This procedure is not as important for diagnosis of tendinopathy as it is for ruling out a tear. If the patient cannot provide good effort to abduction during the physical

examination, the clinician can inject the anesthetic into the subacromial space. After the injection, if there is significant reduction in the pain level and the patient can provide adequate and nearly maximal abduction, tendinopathy is more likely than a rotator cuff tear [10,13,14].

Treatment

Initial

There are five basic phases of treatment (Table 16.1). These phases may overlap and can be progressed as rapidly as tolerated, but each should be performed to speed recovery and to prevent reinjury.

Initially, pain control and inflammation reduction are required to allow progression of healing and the initiation of an active rehabilitation program. This can be accomplished with a combination of relative rest from aggravating activities, icing (20 minutes three or four times a day), and electrical stimulation. Acetaminophen may help with pain control. Nonsteroidal anti-inflammatory drugs are avoided because of their negative effect on tendon healing. Having the patient sleep with a pillow between the trunk and arm will decrease the tension on the supraspinatus tendon and prevent compromise of blood flow in its watershed region.

Rehabilitation

Physical therapy may also help with pain management. Initially, gentle, passive, prolonged stretch may be needed. The use of ultrasound should be closely monitored to avoid heating of an inflamed tendon, which will worsen the situation. Postoperative rehabilitation will progress in a similar fashion once initial healing has occurred and at the discretion of the surgeon.

Restoration of Shoulder Range of Motion

After the pain has been managed, restoration of shoulder motion can be initiated. The focus of treatment in this early stage is on improvement of range, flexibility of the posterior capsule, postural biomechanics, and restoration of normal scapular motion. Codman pendulum exercises, wall walking, stick or towel exercises, and a physical therapy program are useful in attaining full pain-free range of motion. It is important to address any posterior capsular tightness because it can cause anterior and superior humeral head migration, resulting in impingement. A tight posterior capsule and the imbalance it causes force the humeral head anteriorly, producing shearing of the anterior labrum and

Differential Diagnosis

- Rotator cuff tear
- Glenolabral tear
- Muscle strain
- Subacromial bursitis
- Bicipital tendinopathy
- Myofascial pain
- Fracture
- Acromioclavicular sprain
- Tumor
- Myofascial or vascular thoracic outlet syndrome
- Cervical radiculopathy
- Traumatic or atraumatic brachial plexus disease (e.g., Parsonage-Turner [acute brachial neuritis])
- Suprascapular neuropathy
- Thoracic outlet syndrome

Table 16.1 Treatment Phases for Rotator Cuff Tendinopathy

- Pain control and reduction of inflammation
- Restoration of normal shoulder motion, both scapulothoracic and glenohumeral
- Normalization of strength and dynamic muscle control
- Proprioception and dynamic joint stabilization
- Sport- or task-specific training

causing additional injury [25]. Stretching of the posterior capsule is a difficult task. The horizontal adduction that is usually performed tends to stretch the scapular stabilizers, not the posterior capsule. However, stretching of the posterior capsule is possible if care is taken to fix and to stabilize the scapula, preventing stretching of the scapulothoracic stabilizers.

Postural biomechanics are important because with poor posture (e.g., excessive thoracic kyphosis and protracted shoulders), there is increased acromial space narrowing, resulting in greater risk for rotator cuff impingement [26,27]. Restoration of normal scapular motion is also essential because the scapula is the platform on which the glenohumeral joint rotates [28,29]. Thus, an unstable scapula can secondarily cause glenohumeral joint instability and resultant impingement. Scapular stabilization includes exercises such as wall pushups and biofeedback (visual and tactile) [30].

Strengthening

The third phase of treatment is muscle strengthening, which should be performed in a pain-free range of motion. Strengthening should begin with the scapulothoracic stabilizers and the use of shoulder shrugs, rowing, and pushups, which will isolate these muscles and help return smooth motion, allowing normal rhythm between the scapula and the glenohumeral joint. This will also provide a firm base of support on which the arm can move. Attention is then turned to strengthening of the rotator cuff muscles. Positioning of the arm at 45 and 90 degrees of abduction for exercises prevents the “wringing out” phenomenon that hyperadduction can cause by stressing the tenuous blood supply to the tendon of the exercising muscle. The thumbs down position with the arm in more than 90 degrees of abduction and internal rotation should also be avoided to minimize subacromial impingement. After the scapular stabilizers and rotator cuff muscles are rehabilitated, the prime movers are addressed to prevent further injury and to facilitate return to prior function.

There are many ways to strengthen muscles. The rehabilitation program should start with static exercises and co-contractions, progress to concentric exercises, and be completed with eccentric exercises. A therapy prescription should include the number of repetitions, the number of sets, and the intensity at which the specific exercise should be performed. When strength is restored, a maintenance program should be continued for fitness and prevention of reinjury. Local muscle endurance should also be trained.

Proprioception

The fourth phase is proprioceptive training. This is important to retrain the neurologic control of the strengthened muscles, providing improved dynamic interaction and coupled execution of tasks for harmonious movement of the shoulder and arm [31,32]. Tasks should begin with closed kinetic chain exercises (e.g., exercises done with the hand in contact with a fixed object like a wall) to provide joint stabilizing forces [33,34]. As the muscles are reeducated, exercises can progress to open chain activities, such as dumbbell exercises, that may be used in specific sports or tasks. In addition, proprioceptive neuromuscular facilitation is designed to stimulate muscle-tendon stretch receptors for reeducation [35].

Task or Sport Specific

The last phase of rehabilitation is to return to task- or sport-specific activities [36,37]. This is an advanced form of training for the muscles to relearn prior activities. This is important and should be supervised so the task is performed correctly and the possibility of reinjury or injury in another part of the kinetic chain from improper technique is eliminated [38]. The rehabilitation begins at a cognitive level but must be repeated so that it transitions to unconscious motor programming [11].

Procedures

A subacromial injection of anesthetic can be beneficial in differentiating a rotator cuff tear from tendinopathy. Patients with pain that limits the validity of their strength testing may be able to provide almost full resistance to abduction and external rotation after the injection, suggesting rotator cuff tendinopathy. On the other hand, if there is continued weakness, one must consider a rotator cuff tear.

Many clinicians include a corticosteroid with the anesthetic to avoid the need for a second injection. This procedure can be both diagnostic and therapeutic. If one makes the diagnosis of rotator cuff tendinopathy, the corticosteroid injection will decrease the inflammation and allow accelerated rehabilitation. Moreover, a percutaneous tenotomy can be performed under ultrasound guidance. The needle is localized and placed in and out of the tendon to create small perforations within the damaged tendon. This stimulates the healing response through the inflammatory cascade, enhancing tendon repair.

Refer to the injection procedure in Chapter 14.

Surgery

Surgery should be considered if the patient fails to improve with a progressive nonoperative therapy program of 3 to 6 months. Surgical procedures may include subacromial decompression arthroscopically or, less commonly, open. At that time, the surgeon may débride the tendon and explore for other pathologic changes [14,39,40].

Potential Disease Complications

The greatest risk in not treating rotator cuff tendinopathy is rupture or tear of a tendon or the development of a labral tear. As previously discussed, with prolonged impairment in motion and strength and subtle instability, hooking of the acromion can develop. Adhesive capsulitis may develop with chronic pain and decreased shoulder movement as well [18,41-44].

Potential Treatment Complications

There are minimal possible complications from nonoperative treatment of rotator cuff tendinopathy. Because nonsteroidal anti-inflammatory drugs are used frequently, one must remain vigilant to their potential side effects (e.g., gastritis, ulcers, renal impairment, bronchospasm). Injections may cause rupture of the diseased tendon.

Rotator Cuff Tear

Jay E. Bowen, DO

Gerard A. Malanga, MD

Synonyms

Shoulder tear
Torn shoulder

ICD-9 Codes

726.10 Rotator cuff syndrome
727.61 Nontraumatic complete rupture of
rotator cuff
840.4 Rotator cuff sprain

ICD-10 Codes

M75.100 Unspecified rotator cuff tear or
rupture of unspecified shoulder,
nontraumatic
M75.101 Unspecified rotator cuff tear
or rupture of right shoulder,
nontraumatic
M75.102 Unspecified rotator cuff tear
or rupture of left shoulder,
nontraumatic
S43.421 Sprain of right rotator cuff
S43.422 Sprain of left rotator cuff
S43.429 Sprain of unspecified rotator cuff

Definition

The rotator cuff has three main functions in the shoulder. It compresses the humeral head into the fossa, increases joint contact pressure, and centers the humeral head on the glenoid. Three types of tears can occur to the rotator cuff. A full-thickness tear can be massive and cause immediate functional impairments. Another type of tear, a partial-thickness tear, can be broken down into a tear on the superior surface into the subacromial space or a tear on the inferior surface on the articular side. As a result of a rotator cuff tear, the humeral head will be displaced superiorly during abduction because of the unopposed action of the deltoid. These tears can be either traumatic or degenerative [1–7] (Figs. 17.1 to 17.3).

Traumatic tears occur in the younger population of athletes and laborers, whereas degenerative tears occur in older individuals. One reason that rotator cuff tears are more common in men is because there are more male heavy laborers. The incidence of degenerative tears is increased in both sexes for individuals older than 35 years and for those with chronic impingement syndrome, repetitive microtrauma, tendon degeneration, and hypovascularity [4,6,8].

Symptoms

Symptoms are similar to those of rotator cuff tendinitis. Pain is referred to the lateral triceps and sometimes more globally in the shoulder. There is often coexisting inflammation, and the pain quality is dull and achy. Weakness occurs because of the pain, which is caused by the impaired motion or the tear itself. Persons have difficulty with overhead activities. Patients may report pain at night in a side-lying position.

Physical Examination

Examination is essentially the same as for rotator cuff tendinitis. The most common physical findings of a tear are supraspinatus weakness, external rotator weakness, and impingement. The arm drop test may demonstrate greater weakness than expected from an inflamed, intact tendon, although one can be easily fooled. As with rotator cuff tendinitis, an anesthetic injection into the subacromial space may help discern tear. Even though the pain may be improved or resolved from the injection, resisted abduction will be just as weak because the torn tendon cannot withstand the stress [9].

Remember to examine the cervical spine to avoid missing underlying pathologic changes. A rotator cuff tear develops in some individuals as a result of a radiculopathy or other nerve impairment. The dysfunction of the shoulder from a radiculopathy or suprascapular neuropathy results in weakness of the rotator cuff or the scapular stabilizers. This dysrhythmia causes impingement of the tendons with other structures and eventually leads to fraying and tearing [10–12].

Functional Limitations

The greatest limitation that patients complain of is performing overhead activities [2,7,13–15].

FIGURE 17.1 Muscles of the rotator cuff, posterior (A) and anterior (B) views. (From Snider RK. *Essentials of Musculoskeletal Care*. Rosemont, Ill, American Academy of Orthopaedic Surgeons, 1997.)

FIGURE 17.2 Rotator cuff tear with extension of contrast material into the subacromial (short arrow) and subdeltoid (long arrow) bursae. (From West SG. *Rheumatology Secrets*. Philadelphia, Hanley & Belfus, 1997:373.)

Patients with rotator cuff tendinitis complain of difficulty with overhead activities (e.g., throwing a baseball, painting a ceiling), greatest above 90 degrees of abduction, secondary to pain or weakness. Internal and external rotation may be compromised and may affect daily self-care activities. Women typically have difficulty hooking the bra in back. Work activities, such as filing, hammering overhead, and lifting, will be affected. The patient can be awakened by pain in the shoulder, which impairs his or her sleep.

Diagnostic Studies

The diagnosis of a rotator cuff tear depends mostly on the history and physical examination. However, imaging studies may be used to confirm the clinician's diagnosis and to eliminate other possible pathologic processes.

Radiographs are often obtained to rule out any osseous problem. A tear can be inferred if there is evidence of humeral head upward migration or sclerotic changes at the greater tuberosity where the tendons insert. Radiographs

FIGURE 17.3 A, Normal shoulder magnetic resonance image. The supraspinatus tendon is uniformly low signal and continuous (arrows). The space between the humeral head and the acromion (a) is maintained. B, Chronic rotator cuff tear. The supraspinatus tendon is completely torn and retracted to the level of the glenohumeral joint (arrow), where it is surrounded by fluid. Note the high-riding humeral head, close to the acromion. This is due to the atrophy of the cuff muscles associated with chronic tendon tears.

are helpful with active 90-degree abduction showing a decreased acromiohumeral distance secondary to absence of the supraspinatus and unopposed action of the deltoid.

Magnetic resonance imaging (MRI) of the shoulder is the “gold standard.” [16] Computed tomographic scans show osseous structures better but are less effective at demonstrating a soft tissue injury. By evaluation of the amount of retraction, the clinician is also better able to predict the course of recovery.

As in the evaluation of a person with rotator cuff tendinitis, an anesthetic injection can be performed to differentiate a tear from tendinitis.

Shoulder arthrography is performed less often since the advent of MRI. Arthrography involves injection of contrast material into the glenohumeral joint followed by plain radiography. Dye should remain contained in the joint space. If it extravasates, this signifies a tear. Partial-thickness rotator cuff tears can be missed, especially tears on the superior surface. Some centers have been combining gadolinium dye injections with MRI. This is used mostly to identify a labral tear, not a rotator cuff tear.

Ultrasound imaging can also be used in the diagnosis of full-thickness rotator cuff tears [17]. Ultrasonography is becoming more popular in the United States, and it can be a very helpful study when it is performed in centers with clinicians who have experience in musculoskeletal ultrasound imaging. It is now believed that ultrasonography is as accurate as MRI in the diagnosis of supraspinatus tendon tears. Full-thickness tears appear hypoechoic or anechoic where fluid has replaced the area of torn tendon. Manual compression will be able to displace the fluid. In an area of torn tendon without fluid, compression will show the “sagging peribursal fat” sign.*

Diagnostic arthroscopy is done in some instances but is not generally necessary.

Differential Diagnosis

Non-neurologic

- Rotator cuff tendinitis
- Glenolabral tear
- Acromioclavicular sprain
- Occult fracture
- Osteoarthritis
- Rheumatoid arthritis
- Adhesive capsulitis
- Myofascial pain syndrome
- Myofascial thoracic outlet syndrome

Neurologic

- Cervical radiculopathy
- Brachial plexopathy
- Suprascapular neuropathy
- Neurogenic (true) thoracic outlet syndrome

Treatment

Initial

Initial treatment of a rotator cuff tear is similar to that of rotator cuff tendinitis (see Chapter 16). However, if the symptoms do not respond to a rehabilitation program, the clinician should consider surgical consultation earlier in the course of injury.

Rehabilitation

Because of the interrelationship of instability and impingement previously discussed, there is a great deal of overlap in the rehabilitation of these shoulder problems. Treatment must be individualized and based on the restoration of optimal *function*, not merely surgical correction of anatomic changes. Supervised physical therapy is the mainstay of treatment and is successful in most patients.

The basic phases of rehabilitation include the following [12]: pain control and reduction of inflammation; restoration of normal shoulder motion, both scapulothoracic and glenohumeral; normalization of strength and dynamic joint stabilization; proprioception and dynamic joint stabilization; and sport-specific training. The rehabilitation phases may overlap and can be progressed as rapidly as tolerated, but all should be performed to speed recovery and to prevent reinjury.

Pain Control and Reduction of Inflammation

Initially, pain control and inflammation reduction are required to allow progression of healing and the initiation of an active rehabilitation program. These can be accomplished with a combination of relative rest, icing (20 minutes, three or four times a day), electrical stimulation, and acetaminophen or a nonsteroidal anti-inflammatory drug. The next section's rehabilitation program can be added as tolerated by the patient. Having the patient sleep with a pillow between the trunk and the arm will decrease the tension on the supraspinatus tendon and prevent compromise of blood flow in its watershed region.

Restoration of Shoulder Range of Motion

As with all musculoskeletal disorders, the entire body must be taken into consideration. Abnormalities in the kinetic chain can also affect the shoulder. If there are restrictions or limitations in range of motion or strength, the forces will be transmitted to other portions of the kinetic chain, resulting in an overload of those tissues and possibly injury.

After the pain has been managed, restoration of motion can be initiated. The use of Codman pendulum exercises, wall walking, stick or towel exercises, or a physical therapy program is beneficial in attaining full pain-free range. It is important to address any posterior capsular tightness because this can cause anterior and superior humeral head migration, resulting in impingement. A tight posterior capsule and the imbalance it causes force the humeral head anteriorly, producing shearing of the anterior labrum and causing an additional injury. Stretching of the posterior capsule is a difficult task. The horizontal adduction that is usually performed tends to stretch the scapular stabilizers rather than the posterior capsule. If care is taken to fix and to stabilize the scapula and therefore to prevent the stretching of the scapulothoracic stabilizers, stretching of the posterior capsule can be achieved. The focus of treatment in this early stage should be on improving range and flexibility of the posterior capsule, improving postural biomechanics, and restoring normal scapular motion.

Initially, ultrasound to the posterior capsule followed by gentle, passive prolonged stretch may be needed. The use of ultrasound should be closely monitored to prevent heating of an inflamed tendon, which will worsen the injury.

*References 4,6,8,9,12,13,18,19.

Postural biomechanics are important because with poor posture (e.g., excessive thoracic kyphosis and protracted shoulders), there is increased outlet narrowing, resulting in greater risk for rotator cuff impingement. Restoration of normal scapular motion is also essential because the scapula is the platform on which the glenohumeral joint rotates [20,21]. Thus, an unstable scapula can secondarily cause glenohumeral joint instability and resultant impingement. Scapular stabilization includes exercises such as wall push-ups and biofeedback (visual and tactile).

Strengthening

The third phase of treatment is strengthening, and it should be performed in a pain-free range. Strengthening should begin with the scapulothoracic stabilizers and the use of shoulder shrugs, rowing, and pushups, which will isolate these muscles and help return smooth motion, allowing normal rhythm between the scapula and the glenohumeral joint. This will also provide a firm base of support on which the arm can move. Attention should then be turned toward strengthening of the rotator cuff muscles. Positioning of the arm at 45 and 90 degrees of abduction for exercises prevents the “wringing out” phenomenon that hyperadduction can cause by stressing the tenuous blood supply to the tendon of the exercising muscle. The thumbs down position with the arm in greater than 90 degrees of abduction and internal rotation should also be avoided to minimize subacromial impingement. After the scapular stabilizers and rotator cuff muscles are rehabilitated, the prime movers should be addressed to prevent further injury and to facilitate return to prior function.

There are many ways by which to strengthen muscles. The rehabilitation program should start with static contractions and co-contractions, progress to concentric exercises, and be completed with eccentric exercises and endurance training. The BodyBlade (www.BodyBlade.com) can be used for co-contraction in multiple planes and positions for rhythmic stabilization. There are many techniques to strengthen muscles, including static and dynamic exercises. A therapy prescription should include the number of repetitions, the number of sets of repetitions, and the intensity at which the specific exercise should be performed. When strength is restored, a maintenance program should be continued for fitness and prevention of reinjury.

Proprioception

The fourth phase is proprioceptive training. This is important to retrain the neurologic control of the strengthened muscles in providing improved dynamic interaction and coupled execution of tasks for harmonious movement of the shoulder and arm. Tasks should begin with closed kinetic chain exercises to provide joint stabilizing forces. As the muscles are reeducated, exercises can progress to open chain activities that may be used in specific sports or tasks. Exercises such as those using the BodyBlade or plyometrics will also address proprioception. In addition, proprioceptive neuromuscular facilitation is designed to stimulate muscle-tendon stretch receptors for reeducation. Kabat [22] has described shoulder proprioceptive neuromuscular facilitation techniques in detail.

Task or Sport Specific

The last phase of rehabilitation is to return to task- or sport-specific activities. This is an advanced form of training for the muscles to relearn prior activities. This is important and should be supervised so that the task performed is correct and the possibility of reinjury or injury in another part of the kinetic chain from improper technique is eliminated. The rehabilitation begins at a cognitive level but must be practiced so that it ultimately becomes part of unconscious motor programming.

Procedures

Subacromial injections of anesthetic and corticosteroid may be both diagnostic and therapeutic (see Chapter 16).

Surgery

If the patient's condition has not progressed with a conservative rehabilitation after 2 to 3 months, a surgical consultation should be considered. If the patient is unable to perform all the activities he or she demands (vocationally and avocationally) after 6 months of treatment and independent exercise performance, a surgical consultation should be obtained. If the patient is a high-level athlete or worker, earlier consultation may be appropriate. The population of younger patients is more amenable to surgical intervention [6,8].

If surgery is contemplated, repair, débridement, decompression, or a combination of these may be considered. A concomitant injury should be considered, such as a labral tear. The detail of these surgical procedures is beyond the scope of this text.

Potential Disease Complications

Partial rotator cuff tears can progress to full-thickness tears, especially if untreated. Rehabilitation attempts to restore biomechanics close to normal to prevent excessive wear on the tendon, which can cause further degeneration. Chronic untreated rotator cuff tears can lead to shoulder arthropathy [6,11].

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. There are minimal disadvantages to coordinating a rehabilitation program that may improve the patient's symptoms to a level at which the patient is satisfied and functional. However, an overly aggressive program can progress a partial tear to a complete tear. With surgery, in general, the potential problems include bleeding, infection, worsening of the complaints, and nerve injury.

Definition

Scapular winging refers to prominence of the vertebral (medial) border of the scapula [1]. The inferomedial border can also be rotated or displaced away from the chest wall. This well-defined medical sign was first described by Velpeau [2] in 1837. It is associated with a wide array of medical conditions or injuries that typically result in dysfunction of the scapular stabilizers and rotators and, ultimately, glenohumeral and scapulothoracic biomechanics.

Fiddian and King [1] classified scapular winging as either static or dynamic after examination of 25 patients with 23 different causes of scapular winging. Static winging is attributable to a fixed deformity in the shoulder girdle, spine, or ribs; it is characteristically present with the patient's arms at the sides. Dynamic winging is ascribed to a neuromuscular disorder; it is produced by active or resisted movement and is usually absent at rest. Scapular winging has also been classified anatomically according to whether the etiology of the lesion is related to nerve, muscle, bone, or joint disease (Table 18.1).

The scapula is a triangular bone that is completely surrounded by muscles and attaches to the clavicle by the coracoclavicular ligaments and acromioclavicular joint capsule. Motion of the scapula along the chest wall occurs through the action of the muscle groups that originate or insert on the scapula and proximal humerus. These muscles include the rhomboids (major and minor), trapezius, serratus anterior, levator scapulae, and pectoralis minor. The rotator cuff and deltoid muscles are involved with glenohumeral motion. Innervation of these muscle groups includes all the roots of the brachial plexus and several peripheral nerves. Scapular winging may be caused by brachial plexus injuries but most often is related to a peripheral nerve injury (see Table 18.1).

Injury to the long thoracic and spinal accessory nerves with weakness of the serratus anterior and trapezius muscles, respectively, is most commonly associated with scapular winging. The serratus anterior muscle originates on the outer surface and superior border of the upper eight or nine ribs and inserts on the costal surface of the medial border of the scapula. It abducts the scapula and rotates it so the glenoid cavity faces cranially and holds the medial border of the scapula against the thorax.

The serratus anterior muscle is innervated by the pure motor long thoracic nerve, which arises from the ventral rami of the fifth, sixth, and seventh cervical roots. The nerve passes through the scalenus medius muscle, beneath the brachial plexus and the clavicle, and over the first rib. It then runs superficially along the lateral aspect of the chest wall to supply all the digitations of the serratus anterior muscles [26]. Because of its long and superficial course, the long thoracic nerve is susceptible to both traumatic and non-traumatic injuries (Fig. 18.1).

The trapezius muscle consists of upper, middle, and lower fibers. The upper fibers originate from the external occipital protuberance, superior nuchal line, nuchal ligament, and spinous process of the seventh cervical vertebra and insert on the lateral clavicle and acromion. The middle fibers arise from the spinous process of the first

through fifth thoracic vertebrae and insert on the superior lip of the scapular spine. The lower fibers originate from the spinous process of the sixth through twelfth thoracic vertebrae and insert on the apex of the scapular spine. They are innervated by the pure motor spinal accessory nerve (cranial nerve XI) and afferent fibers from the second through fourth cervical spinal nerves. The root fibers unite to form a common trunk that ascends to enter the intracranial cavity through the foramen magnum. It exits with the vagus nerve through the jugular foramen, pierces the sternocleidomastoid muscle, and descends obliquely across the floor of the posterior triangle of the neck to the trapezius muscle [26]. In the posterior triangle, the nerve lies superficially, covered only by fascia and skin, and is susceptible to injury. Cadaver studies have shown considerable variations in the course and distribution of the spinal accessory nerve in the posterior triangle and in the nerve's relationship to the borders of the sternocleidomastoid and trapezius muscles [27]. The trapezius muscle adducts the

scapula (middle fibers), rotates the glenoid cavity upward (upper and lower fibers), and elevates and depresses the scapula. Overall, the trapezius muscles maintain efficient shoulder function by both supporting the shoulder and stabilizing the scapulae (Fig. 18.2).

A rare cause of scapular winging is dorsal scapular nerve palsy. The dorsal scapular nerve is a pure motor nerve from the fifth cervical spinal nerve that supplies the rhomboid and levator scapulae muscles. It arises above the upper trunk of the brachial plexus and passes through the middle scalene muscle on its way to the levator scapulae and rhomboids. The rhomboids (major and minor) adduct and elevate the scapula and rotate it so the glenoid cavity faces caudally [26].

The levator scapulae muscles originate on the transverse process of the first four cervical vertebrae and insert on the medial borders of the scapulae between the superior angle and the root of the spine. They elevate the scapulae and assist in rotation of the glenoid cavity caudally. They are

FIGURE 18.1 Anterolateral view of the right upper chest and shoulder showing the course of the long thoracic nerve and innervation of the serratus anterior muscles. Note the superficial location of the long thoracic nerve. (From the Mayo Foundation for Medical Education and Research. © Mayo Foundation, 2007.)

innervated by the dorsal scapular nerve (emanating from the fifth cervical spinal nerve) and the cervical plexus (emanating from the third and fourth cervical spinal nerves) (Fig. 18.3).

Symptoms

A patient's presenting symptoms depend on the type and chronicity of the injury. Most patients, however, complain of upper back or shoulder pain, muscle fatigue, and weakness with use of the shoulder. The diagnosis of scapular winging is made clinically. A pain profile should be obtained, including onset and duration of pain, location, severity, and quality as well as exacerbating and relieving factors, not only to provide baseline information but also to help develop a differential diagnosis. The patient should also be questioned about hand dominance because the dominant shoulder is usually more muscular but sits lower than the nondominant shoulder. Knowledge of the patient's age, occupation and hobbies, and current and previous level of functioning may also contribute to the diagnosis and treatment plan. The mechanism of injury in patients with traumatic palsy is important, as are associated findings including muscle spasm, paresthesia, and muscle wasting or weakness [28,29]. The scapular winging of long thoracic neuropathy and serratus anterior muscle weakness must be distinguished from that of a spinal accessory neuropathy and trapezius muscle weakness as well as dorsal scapular neuropathy and rhomboid weakness. Serratus anterior muscle dysfunction is the most common

FIGURE 18.2 Lateral view of the neck showing the course of the spinal accessory nerve and innervation of the trapezius muscle. (From the Mayo Foundation for Medical Education and Research. © Mayo Foundation, 2007.)

FIGURE 18.3 View of upper back showing origins and insertions of rhomboid, levator scapulae, and trapezius muscles. (From the Mayo Foundation for Medical Education and Research. © Mayo Foundation, 2007.)

cause of scapular winging. Typically, patients complain of a dull aching pain in the shoulder and periscapular region. The periscapular pain may be related to spasm from unopposed contraction of the other scapular stabilizers in the presence of serratus anterior muscle weakness. There may be “clicking” or “popping” noise emanating from the periscapular area when the patient moves, which is made worse with

stressful upper extremity activities [28]. Because the serratus anterior muscle rotates the scapula forward as the arm is abducted or forward flexed above the shoulder level, these movements are affected. Shoulder fatigue and weakness are related to loss of scapular rotation and stabilization.

A cosmetic deformity may occur in the upper back as a result of the winged scapula. It may be apparent at rest but usually is more obvious on raising of the arm. Patients may find it difficult to sit for prolonged periods with the back resting against a hard surface, such as driving for long periods.

With trapezius muscle weakness, the affected shoulder is depressed, and the inferior scapular border rotates laterally, which makes prolonged use of the arm painful and tiresome. Patients often complain of a dull ache around the shoulder girdle and difficulty with overhead activities and heavy lifting, especially with shoulder abduction greater than 90 degrees [29].

Physical Examination

The patient should be suitably undressed so that the examiner can observe, both front and back, the normal bone and soft tissue contours of both shoulders and scapulae for symmetry and their relationship to the thorax. The patient's overall posture is assessed, as are the presence of muscle spasm and trapezius or rhomboid muscle atrophy. Scapulothoracic motion is examined with both passive and active range of motion activities of the shoulder. The different patterns of scapulothoracic movement can assist in the differential diagnosis of scapular winging and are illustrated in Figures 18.4 to 18.6 [30].

FIGURE 18.4 Winging of the right scapula with forward flexion of the extended arms due to injury of the long thoracic nerve with serratus anterior weakness. Note the upward displacement of the scapula with prominence of the vertebral border and medial displacement of the inferior angle. (From the Mayo Foundation for Medical Education and Research. © Mayo Foundation, 2007.)

With long thoracic neuropathy and serratus anterior muscle weakness, the cardinal sign is winging of the scapula, in which the vertebral border of the scapula moves away from the posterior chest wall and the inferior angle is rotated toward midline. This scapular winging may be visible with the patient standing normally, but if the weakness is mild, it may

FIGURE 18.5 Right spinal accessory nerve palsy with trapezius weakness. The neckline is asymmetric, the shoulder droops, and there is lateral displacement of the superior angle of scapula with the glenoid labrum rotated downward. (From the Mayo Foundation for Medical Education and Research. © Mayo Foundation, 2007.)

FIGURE 18.6 Dorsal scapular nerve palsy with rhomboid weakness. There is lateral displacement of the inferior angle of the right scapula that is accentuated when the patient pushes his elbows backward against resistance. Note atrophy of the rhomboid and infraspinatus muscles. (From the Mayo Foundation for Medical Education and Research. © Mayo Foundation, 2007)

be visible only when the patient extends the arm and pushes against a wall in a pushup position (Fig. 18.4) [3,28,31].

Spinal accessory neuropathy and trapezius muscle weakness are usually accompanied by an asymmetric neckline with noticeable shoulder droop when the patient's arms are unsupported at the sides. On the affected side, deepening of the supraclavicular fossa is evident and shoulder shrug is difficult. With shoulder elevation, the scapula is displaced laterally, rotating downward and outward. There is usually difficulty with shoulder abduction above 90 degrees, more so than with forward flexion. Weakness with attempted shoulder elevation against resistance is characteristic. Normal muscle testing can elicit weakness in the trapezius muscle (Fig. 18.5) [29,32].

With weakness of the rhomboids, winging of the scapula is usually minimal. There is lateral displacement of the inferior angle of the scapula that is best accentuated when the patient pushes the elbow backward against resistance or slowly lowers the arms from a forward elevated position. Atrophy of the rhomboids may be present. The scapula is displaced downward and laterally (Fig. 18.6) [32].

A complete neurologic and musculoskeletal examination, with manual muscle strength testing and sensory and reflex testing, should be completed to rule out underlying neuromuscular disease processes. In addition, thorough examination of the neck and shoulder with provocative maneuvers should be completed to rule out additional musculoskeletal sources of scapular winging.

Functional Limitations

Functional limitations depend not only on the cause of the scapular winging but also on the severity of weakness and pain. Difficulty with activities of daily living may be evident as a result of pain, weakness, and altered scapulohumeral and glenohumeral motion. Especially affected are activities that require arm elevation above the level of the shoulder (e.g., brushing hair or teeth or shaving). Recreational and vocational activities such as golf, tennis, and volleyball that entail working or reaching overhead may be affected. Chronic shoulder pain and dysfunction can lead to depression and anxiety, irritability, concentration difficulties, lack of sleep, and chronic fatigue. Overuse of the shoulder and scapular stabilizer muscles can lead to myofascial pain syndromes.

Diagnostic Studies

Plain radiography of the shoulder, cervical spine, chest, and scapulae is recommended as part of the initial evaluation for scapular winging, especially if the cause is not obvious. Plain radiography can help rule out other causes of scapular winging, such as subscapular osteochondroma, avulsion fracture of the scapula, or other primary shoulder and cervical spine disease. With radiographs of the scapula, oblique views are recommended because osteochondroma may be hidden on anteroposterior views [33].

Computed tomography and magnetic resonance imaging are usually not necessary unless the coexistence of other disease processes is suspected. The patient's presentation and examination findings are pivotal in deciding whether advanced imaging is necessary.

Electrodiagnostic studies, namely, electromyography and nerve conduction studies, are valuable tools clinically to aid in the evaluation of scapular winging. They can assist in localizing injury and disease of peripheral nerves or muscles related to scapular function. These studies can help evaluate patients with abnormal scapulohumeral motion but in whom it cannot be clearly established clinically whether the weakness lies in a particular muscle or in the actions of other muscles acting on the scapula.

Serial electromyographic and nerve conduction studies have been used to follow recovery in patients with isolated long thoracic or spinal accessory nerve palsies and to help in decisions of whether to undertake nerve exploration or muscle transfer [28,29]. However, caution has been advised in the use of needle electromyographic findings to predict the prognosis and to guide the timing of surgical repair [34]. Long thoracic and spinal accessory neuropathies may be associated with a good prognosis, irrespective of needle electromyographic findings.

Differential Diagnosis [42]

- Rotator cuff disease
- Shoulder impingement syndromes
- Glenohumeral instability (especially posterior instability)
- Acromioclavicular joint disease
- Shoulder arthritis
- Adhesive capsulitis
- Bicipital tendinitis
- Cervical radiculopathy (especially C5-C7)
- Suprascapular nerve entrapment
- Myofascial pain syndromes
- Scoliosis (associated rib deformities can cause asymptomatic scapular winging on convex side of curve)
- Sprengel deformity (congenital deformity of shoulder with high-riding and downward-rotated scapula, often confused with scapular winging)
- Fracture or malunion of clavicle and acromion
- Tumors of shoulder girdle, lung, or spine

Treatment

In most patients, scapular winging is a result of neurapraxic injuries. Fortunately, these types of injuries usually resolve spontaneously within 6 to 9 months after traumatic injury and within 2 years after nontraumatic injuries. In one study [34], traumatic long thoracic and spinal accessory nerve injuries were associated with a poor prognosis compared with nontraumatic neuropathies. Once the diagnosis is made, conservative treatment should be initiated. Some clinicians have recommended a trial of conservative treatment for at least 12 to 24 months to allow adequate time for nerve recovery [28,29].

Initial

Pain control may be achieved early with use of an analgesic or an anti-inflammatory medication. Activity modification is recommended. The patient should avoid precipitating activities and strenuous use of the involved extremity. Physical modalities, such as ice massage, superficial moist heat, and ultrasound, can be applied to help with pain control. Ice

massage may additionally help control swelling and relieve associated muscle spasm [32].

Immobilization should be a part of the initial management to prevent overstretching of the weakened muscle [35]. This can be accomplished with the use of a sling to rest the arm until the patient can recover brace-free shoulder flexion or have reduced pain. In one study, this could be anywhere from 1 to 7 months [36].

Long-term use of scapular winging shoulder braces to maintain the position of the scapula against the thorax is controversial. Various shoulder braces and orthotics have been used with mixed results. Some authors [8,31] recommend against use of shoulder braces because they are cumbersome, poorly tolerated, and ineffective. Others have advocated their use to protect against muscle overstretching and scapulothoracic overuse [32,35]. One author reported successful treatment of a brachial plexus injury and winged scapula with use of Kinesio tape and exercise to facilitate the rotator cuff groups and scapular stabilizers [36].

Rehabilitation

Specific treatment varies, depending on the etiology of the scapular winging. In general, range of motion exercises should be initiated early to prevent contractures or adhesive capsulitis, especially if the affected extremity is immobilized.

A stretching and strengthening exercise program can be undertaken after pain control is achieved [32]. Stretching the scapular stabilizers and shoulder capsules without overstretching the weakened muscle as well as cross-body adduction to stretch the rhomboids is important and should be supervised by a physical therapist. The scapular stabilizer, cervical muscles, and rotator cuff muscle should be strengthened, especially the affected muscle groups. This can be accomplished by passive scapular retraction, such as scapular squeeze. Isometric strengthening exercises can include scapular protraction and retraction, shoulder packing, and shoulder shrugs to strengthen the pectoralis, serratus anterior, rhomboids, upper trapezius, and levator scapulae. Advanced exercises can include specific rotator cuff strengthening as well as shoulder circles with a ball against a wall, stabilizing ball pushups, resistance band pull-aparts and pull-downs, and chest presses both standing and lying down. Neuromuscular electrical stimulation may be used to prevent muscle atrophy. Functional glenohumeral and scapulothoracic muscle patterns must be relearned. Progression to an independent structured home exercise program is recommended, but the patient should first be able to perform the exercises appropriately under supervision of a physical therapist.

Procedures

Localized injections are not routinely administered for isolated scapular winging. Injection therapy may be indicated for other coexisting shoulder disease to help with pain control.

Surgery

Conservative treatment has been recommended for a prolonged period (12 to 24 months) to allow adequate time for

recovery before surgical options are considered. [28,29,37] Surgery should be considered for patients who do not recover in this time. In patients with penetrating trauma in which the nerve may have been injured, spontaneous recovery is less likely, and early nerve exploration with neurolysis, direct nerve repair, or nerve grafting may be indicated.

Surgery may also be indicated if scapular winging appears to have been caused by a surgically treatable lesion (e.g., a subscapular osteochondroma) and the patient is symptomatic or has a cosmetic disfigurement [22,38]. In general, surgical options are many but can be divided into two categories: static stabilization procedures and dynamic muscle transfers.

Static stabilization procedures involve scapulothoracic fusion and scapulothoracic arthrodesis in which the scapula is fused to the thorax. These procedures may be effective in cases of generalized weakness (e.g., facioscapulohumeral muscular dystrophy) when the patient has disabling pain and functional loss and no transferable muscles. [32,37,39,40] They can relieve shoulder fatigue and pain and allow functional abduction and flexion of the upper extremity [13,39]. Static stabilization procedures have fallen out of favor for scapular winging related to isolated muscle weakness because the results deteriorate over time with recurrence of winging. The usual incidence of complications associated with some of these procedures is high [32,39]. Dynamic muscle transfers have shown better results for correction of scapular winging and restoration of function. Several different muscles have been used in various muscle transfer techniques to provide dynamic control of the scapula and to improve scapulothoracic and glenohumeral motion. Transfer of the sternal head of the pectoralis major muscle to the inferior angle of the scapula with fascia lata autograft reinforcement is the preferred method of treatment for scapular winging related to long thoracic nerve injury. [32,37,41] The surgical procedure of choice for scapular winging related to chronic trapezius muscle dysfunction involves the lateral transfer of the insertions of the levator scapulae and the rhomboid major and minor muscles. This procedure enables the muscles to support the shoulder girdle and to stabilize the scapula [29,32,37].

Potential Disease Complications

Disease complications are usually related to scapulothoracic dysfunction as a result of scapular winging. This can contribute to glenohumeral instability and subsequent shoulder range of motion and functional deficits as well as chronic periscapular, upper back, and shoulder pain. Secondary impingement syndromes can result from the muscle dysfunction. Adhesive capsulitis can occur from loss of shoulder mobility and function. Cosmetic deformity is a common result of scapular winging, especially if there is a combined serratus anterior and trapezius muscle weakness.

Potential Treatment Complications

Pharmacotherapy can lead to treatment complications. Nonsteroidal anti-inflammatory drugs have well-documented adverse effects that most commonly involve the gastrointestinal system. Analgesics may have adverse effects that predominantly involve the hepatorenal system. These complications

can be minimized by having a working knowledge of the patient's ongoing medical problems, current medications, and potential drug interactions.

Local injections may cause allergic reactions, infection at the injection site, and, rarely, sepsis. Tendon rupture is a potential complication if inadvertent injection into a tendon occurs.

Surgical complications are numerous and include a large, cosmetically unpleasant incision over the shoulder and upper back, postoperative musculoskeletal deformities (e.g., scoliosis), infection, pulmonary complications (e.g., pneumothorax and hemothorax), hardware failure, pseudarthrosis, recurrent winging, and persistent pain.

Definition

Osteoarthritis of the glenohumeral joint occurs when there is loss of articular cartilage that results in narrowing of the joint space (Fig. 19.1). Synovitis and osteocartilaginous loose bodies are commonly associated with glenohumeral arthritis. Pathologic distortion of the articular surfaces of the humeral head and glenoid can be due to increasing age, overuse, heredity, alcoholism, trauma, Gaucher disease (lipid storage disease), or metabolic disease of bone.

In looking at glenohumeral arthritic conditions, one must consider osteonecrosis both as an etiologic entity and as a related endpoint to the disease. Most of the information about osteonecrosis of the humeral head is extrapolated from the research findings of the disorder of the hip. The major difference between osteonecrosis of the hip and osteonecrosis of the humeral head is that the shoulder bears less weight than the hip. Risk factors are corticosteroid use, radiation therapy, and sickle cell anemia, but its presence in a medically uncomplicated adolescent competitive swimmer [1] does seem to suggest that it may be more common than previously thought.

Shoulder osteoarthritis is most commonly seen beyond the fifth decade and is more common in men. Long-standing complete rotator cuff tears, multidirectional instability from any cause, lymphoma [2] (chronic lymphocytic lymphoma or immunocytoma), or prior capsulorrhaphy for anterior instability [3] can predispose to glenohumeral arthritis.

Acute septic arthritis should not be heedlessly ruled out in the face of severe osteoarthritis [4]. The medical history should include any history of fracture, dislocation, rotator cuff tear, repetitive motion, metabolic disorder, immunosuppression, chronic glucocorticoid administration, and prior shoulder surgery.

Symptoms

Symptoms include shoulder pain intensified by activity and partially relieved with rest. Pain is usually noted with all shoulder movements. Major restriction of shoulder motion and disuse weakness or pain inhibitory weakness are common and potentially progressive. Resultant adhesive capsulitis may be the primary clinical presentation. Pain is typically restricted to the area of the shoulder and may be felt around the deltoid region but not typically into the forearm. Pain is

FIGURE 19.1 Osteoarthritis of the shoulder.

generally characterized as dull and aching but may become sharp at the extremes of range of motion; it is typically worse in the supine position and in attempting to sleep on the arthritic side. Pain may interfere with sleep and may be worse in the morning. Neurologic symptoms, such as numbness and paresthesias, should be absent.

Physical Examination

Restriction of shoulder range of motion is a major clinical component, especially loss of external rotation and abduction. Both active and passive range of motion is affected in shoulder arthritis, compared with only active motion in rotator cuff tears (passive range is normal in rotator cuff injuries unless adhesive capsulitis is present). Pain increases when the extremes of the restricted motion are reached, and crepitus is common with movement. Tenderness may be present over the anterior rotator cuff and over the posterior joint line.

Several well-described tests for examination of the shoulder are commonly used in clinical practice (e.g., Neer, Hawkins-Kennedy, Yergason, painful arc, and compression-rotation test). Pooled sensitivity and specificity range from 53% to 95%, yet meta-analysis has demonstrated that use of any single shoulder examination test to make a diagnosis cannot be unequivocally recommended. Combinations of tests provide better accuracy, but marginally so. These findings seem to provide support for stressing a comprehensive clinical examination [5].

If acromioclavicular joint osteoarthritis is an accompanying problem, the acromioclavicular joint may be tender. There may be wasting of the muscles surrounding the shoulder because of disuse atrophy. Sensation and deep tendon reflexes should be normal. In patients with inconsistent physical examination findings and questionable secondary gain issues, the American Shoulder and Elbow Surgeons subjective shoulder scale has demonstrated acceptable psychometric performance for outcomes assessment in patients with shoulder instability, rotator cuff disease, and glenohumeral arthritis [6]. Additional scoring systems, such as the Hospital for Special Surgery score and the validated Western Ontario Osteoarthritis of the Shoulder Index, may be of clinical or research utility [7].

Functional Limitations

Any activities that require upper extremity strength, endurance, and flexibility can be affected. Most commonly, activities that require reaching overhead in external rotation are limited. These include activities of daily living (such as brushing hair or teeth, donning or doffing upper torso clothes) and activities such as throwing or reaching for items overhead. If pain is severe and constant, sleep may be interrupted, sleep-wake cycle disruption may occur, and situational reactive depression is not uncommon, especially with a shoulder pain syndrome that has exceeded 3 months [8].

Diagnostic Studies

Routine shoulder radiographs with four views (anteroposterior internal and external rotation, axillary, and scapular Y) are generally sufficient for evaluating loss of articular cartilage and glenohumeral joint space narrowing (Fig. 19.2). Varying degrees of flattening of the humeral head, marginal osteophytes, calcific tendinitis, subchondral cysts in the humeral head and glenoid, sclerotic bone, bone erosion, and humeral head migration may be seen. Specifically, if there is a chronic rotator cuff tear that is contributing to the destruction of the articular cartilage, the humeral head will be seen pressing against the undersurface of the acromion. Associated acromioclavicular joint arthritis can be seen on the anteroposterior view.

Conventional magnetic resonance imaging is the “gold standard” to assess soft tissues for rotator cuff tear; but when more sensitive evaluation of the labrum, capsule, articular cartilage, and glenohumeral ligaments is required or when a partial-thickness rotator cuff tear is suspected, magnetic resonance arthrography with intra-articular administration of contrast material may be required to visualize these subtle findings [9]. Paralabral cysts (extraneural ganglia), which can result with posterior labrocapsular complex tears and cause suprascapular nerve compression, may be visualized on magnetic resonance imaging [10].

Computed tomography may have a unique role in finding posterior humeral head subluxation relative to the glenoid in the absence of posterior glenoid erosion [11]. A rise in popularity of diagnostic ultrasonography in musculoskeletal medicine is undeniable. The modality may play a role in the diagnosis of full-thickness rotator cuff tear in experienced hands, but significant inter-rater reliability has been

FIGURE 19.2 Radiograph typical of glenohumeral osteoarthritis.

called into question [12,13], and diagnostic ultrasonography would play a minimal role in the diagnosis of glenohumeral arthritic conditions.

Electrodiagnostic medicine consultation will help rule out idiopathic brachial plexopathy (Parsonage-Turner syndrome), cervical radiculopathy, and isolated suprascapular, dorsal scapular, or axillary neuropathy. The sensory irritative component of spinal or peripheral nerve irritation will usually yield a normal result, but H reflexes to median nerve stimulation at the level of the elbow may be suggestive of C5-C6 radiculitis, whereas findings on needle electromyography would be normal.

Complete blood counts, coagulation profile, erythrocyte sedimentation rate, and blood cultures may be in order. In addition, the author encourages that any woman with shoulder pain recalcitrant to seemingly appropriate treatment be considered for mammography.

Differential Diagnosis

- Rotator cuff disease
- Synovitis
- Cervical osteoarthritis
- Shoulder instability
- Rheumatoid arthritis
- Cervical radiculopathy
- Labral degeneration and tear
- Pseudogout
- Charcot joint
- Biceps tendon abnormalities
- Infection
- Fracture of the humerus
- Adhesive capsulitis
- Parsonage-Turner syndrome
- Neoplasms
- Leukemic arthritis
- Avascular necrosis

Treatment

Initial

Shoulder arthritis is a chronic condition, but acute exacerbations in pain can be managed conservatively. Nonsteroidal anti-inflammatory drugs or analgesic medications can help with pain and enable rehabilitation. Capsaicin cream, lidocaine patches, ice, or moist heat may be used topically as needed. Gentle stretching exercises help maintain the range of motion and prevent secondary adhesive capsulitis and sequelae of immobility.

Rehabilitation

The shoulder is a complicated structure composed of several joints with both static and dynamic stabilizers that tend to function, and fail, as a unit. A well-designed rehabilitation program must take this into account and treat glenohumeral arthritic conditions within this context. The rehabilitative efforts are dedicated to the restoration of strength, endurance, and flexibility of the shoulder musculature. Supervised physical or occupational therapy should focus on the upper thoracic, neck, and scapular muscle groups but address the

entire upper extremity kinetic chain, including the rotator cuff, arm, forearm, wrist, and hand. Patients benefit from aquatic therapy and can easily be taught exercises and then transitioned to an independent pool exercise program that they can continue long term. In cases of severe rheumatoid arthritis, joint-sparing static exercises may prevent atrophy and maintain strength of dynamic stabilizers of the shoulder without placing undue stress on the remaining articular surfaces. Joint-sparing exercises such as isometric contraction within normal range of motion will strengthen shoulder stabilizers, minimize joint damage, and decrease induction of the inflammatory cascade that often drives arthritic patients to seek health care. The consensus [14] on glenohumeral involvement in rheumatoid arthritis is that narrowing of the joint space is a turning point indicating a risk of rapid joint destruction, and surgical interventions should be considered before musculoskeletal sequelae are too severe to enable adequate recovery. Postoperative care, although it depends on the operative intervention, should focus on maintenance of functional range of motion and prevention of adhesive capsulitis but be balanced with avoidance of dislocation or damage to the repaired labrum. Range of motion after total shoulder arthroplasty will be considerably less than in the shoulder not operated on. Suprascapular nerve block may have a role in helping the patient tolerate postoperative therapies.

The success of flexibility exercises will be determined by the extent of mechanical bone blockade, which in turn is determined by the magnitude of glenohumeral incongruous distortion, presence of loose bodies, and osteophyte formation. Pain control can be assisted with modalities such as ultrasound and iontophoresis. Electrical stimulation may have a limited role in posterior shoulder strengthening in patients with poor posture and “rounded shoulders” on examination, but it should not take the place of volitional contraction and not be used routinely across arthritic joints. In caring for arthroplasty patients, the Neer protocol for postoperative total shoulder arthroplasty rehabilitation is widely used and based on tradition and the basic science of soft tissue and bone healing [15].

Procedures

If therapies fail or are impossible because of pain, the patient has several options. Periarticular injections may offer some help to control pain of associated problems, such as subacromial bursitis and rotator cuff tendinopathy. Wide variations exist in local anesthetic doses and techniques. On the other hand, steroid doses do not vary as widely with methylprednisolone acetate and triamcinolone acetonide, the most commonly used agents [16]. Intra-articular glenohumeral joint injections may also afford some pain relief, particularly in the early stages. The accuracy of intra-articular injections not fluoroscopically guided is less than perfect at 80%; the anterior approach is slightly more accurate than the posterior approach at 50% [17]. However, injections have not been shown to alter the underlying arthritis pathoanatomy (Fig. 19.3). Great care should be taken in anticoagulated patients. Viscosupplementation (hylan G-F 20) is not approved by the Food and Drug Administration for the glenohumeral joint, but the author has empirically seen it play a role in comprehensive care of mild osteoarthritis.

FIGURE 19.3 Approximate surface anatomy (*insets*) and internal anatomic sites for injection of the glenohumeral joint laterally and anteriorly. (From Lennard TA. *Physiatric Procedures in Clinical Practice*. Philadelphia, Hanley & Belfus, 1995.)

The initial setup can be identical for either intra-articular glenohumeral or subacromial injection. With the patient seated with the arm either in the lap or hanging down by the side, the internal rotation and gravity pull of the arm will open the space, leading to the glenohumeral joint or subacromial space. Several approaches have been described. Most commonly for a subacromial injection, the skin entry point is 1 cm inferior to the acromion, and the needle is tracked anteriorly at a lateral to medial 45-degree angle in the axial plane and slightly superior (under the acromion). The injectate should flow with minimal resistance into this potential space. If resistance is encountered, the needle should be repositioned to avoid intratendinous injection, which can increase the risk of tendon rupture. For glenohumeral injection, a more inferior and medial approach is used (Fig. 19.4).

Postinjection care includes awareness of the local anesthetic effects and avoidance of impingement or maneuvers at end range of motion. Patients are cautioned to avoid aggressive activities for the first few days after the injection. If the adhesive capsulitis component is specifically being treated, a suprascapular nerve block with 5 to 10 mL of 0.25%

FIGURE 19.4 Combined subacromial and suprascapular injection. The site is marked for intra-articular glenohumeral injection.

bupivacaine (Marcaine) with or without epinephrine can be performed immediately before therapy, with an appropriately trained therapist aware of the safe handling of such an anesthetized joint. The author typically employs a combined suprascapular and subacromial approach in these cases and coordinates follow-up appointments with occupational therapy. This should be done only with properly trained therapists who are aware of the postinjection proprioceptive loss.

Surgery

If unacceptable symptoms persist despite conservative treatment, the patient may decide to reduce his or her activity level to minimize pain or proceed with one of a number of surgical interventions. It is important to inform the patient that regardless of the treatment approach, with osteoarthritis, a return to normal shoulder function, by either rehabilitation or surgery, is not possible. However, pain control and some increased function are usually achievable.

Surgical options include débridement of the glenohumeral joint by open or arthroscopic techniques and hemiarthroplasty or total shoulder arthroplasty. If reasonable congruity between the humeral head and glenoid is present, good improvement in pain control and some functional improvement can be anticipated with débridement, even in the presence of severe chondromalacia. The glenoid may be amenable to arthroscopic resurfacing with a meniscal allograft [18]. Other biologic surfaces include anterior capsule, fascia lata autograft, Achilles tendon allograft, and cartilage-preserving arthroscopic spongioplasty [19]. However, inconsistent results and high complication rates are seen, and a trend toward arthroplasty is occurring. Other arthroscopic techniques are successful, provided osteophytes and loose bodies are removed (Fig. 19.5) [20]. Hemiarthroplasty may be indicated in the absence of advanced glenohumeral disease if the glenoid can at least be converted to a smooth concentric surface [21]. Shoulder hemiarthroplasty volumes and rates increased at annual rates of 6% to 13% from 1993 to 2007, with a revision increase from 4.5% to 7%, and procedures are predicted to increase by 192% to 322% by 2015 [22]. Hemiarthroplasty has also been suggested as the procedure of choice in moderate to severe glenohumeral arthritis and irreparable rotator cuff tears [23]; it may have other indications in avascular

FIGURE 19.5 Arthroscopic surgical view of osteoarthritis.

necrosis, glenohumeral chondrolysis, tumor, or complete deltoid denervation with subluxation and secondary osteoarthritis [24].

If major incongruity is present between the humeral head and glenoid, total shoulder arthroplasty may be indicated [25]. There is some suggestion of better long-term outcomes when biceps tenodesis is performed concomitantly with shoulder arthroplasty [26]. Although it may seem counterintuitive, proprioception actually improves after total shoulder arthroplasty over prearthroplasty measurements [27]. This is important from the standpoint of activities of daily life in osteoarthritic patients. Most shoulders, however, can be aided arthroscopically with appropriate technique, which often necessitates a second posterior portal and a highly experienced shoulder arthroscopist [20]. Although a greater risk of more advanced glenohumeral arthritis is associated with arthroscopic procedures that result in limited external rotation [28], arthrodesis may be required for irreversible and non-reconstructible massive rotator cuff tears, tumor, and deltoid muscle denervation as well as for detachment of the deltoid from its origin or to stabilize the glenohumeral joint after many failed attempts at shoulder reconstruction [29]. Arthrodesis for failed prosthetic arthroplasty or tumor resection presents additional challenges and additional risk of the aforementioned complications. A newer procedure, thermal capsulorrhaphy, has come in and out of favor; it is usually used more in high-functioning athletes for isolated posterior instability without labral detachment rather than in isolated glenohumeral osteoarthritis [30].

Potential Disease Complications

Disease complications include chronic intractable pain and loss of shoulder range of motion. These result in diminished functional ability to use the arm, disuse weakness, difficulty with sleep, inability to perform work and recreational activities, and reactive depression. Isolated nerve injury or brachial plexopathy may result.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Infection, hemarthrosis, and allergic reaction to the medications are rare side effects of injections. In particular, there may be an association between subdeltoid septic bursitis and concomitant systemic isotretinoin (Accutane) [31]. Fluid retention or transient hyperglycemia may be seen with a single exogenous glucocorticoid injection. Arthroscopic complications are not common, but the usual possibilities, including neurovascular issues, have been reported. Arthrodesis complications include nonunion, malposition, pain associated with prominent hardware, and periarticular fractures. Arthrodesis after cancer reconstruction has a higher risk of complication [29].

Definition

Suprascapular neuropathy is a demyelinating or axonal injury to the suprascapular nerve. Once considered a diagnosis of exclusion, suprascapular neuropathy is now becoming a well-recognized condition stemming from traction or compression of the nerve at some point along its course. Epidemiologic data are limited, but the prevalence of suprascapular neuropathy is reportedly between 12% and 33% in overhead athletes and between 8% and 100% in patients with massive rotator cuff tears [1].

To understand the pathophysiologic mechanism, it is imperative to have a good knowledge of the anatomy (Fig. 20.1). The suprascapular nerve arises from the upper trunk of the brachial plexus and receives contributions mainly from the fifth and sixth cervical nerve roots, with variable contribution from the fourth cervical nerve root. It courses posterolaterally, deep to the trapezius and clavicle, on its way to the suprascapular notch. Here, it passes beneath the transverse scapular ligament to enter the supraspinous fossa. Within the supraspinous fossa, the suprascapular nerve sends two motor branches to the supraspinatus muscle and receives sensory branches from multiple surrounding structures, including the posterior aspect of the glenohumeral joint, the acromioclavicular joint, and the subacromial bursa. The nerve then courses inferolaterally around the lateral aspect of the scapular spine. This region is referred to as the spinoglenoid notch and is a common area of suprascapular nerve compression. Finally, the nerve enters the infraspinous fossa, where its terminal motor branches innervate the infraspinatus muscle.

The indirect course of the nerve as well as its passage through two notches makes it particularly vulnerable to injury. Static forms of compression or traction can stem from anatomic variations, particularly at the suprascapular notch, where the transverse scapular ligament can hypertrophy or ossify. At the spinoglenoid notch, compression is most frequently due to a space-occupying paralabral cyst that develops as a result of a labral tear [1].

Dynamic forms of suprascapular neuropathy are often seen in overhead athletes because of tightening of the spinoglenoid ligament during the overhead motion [2]. This leads to the so-called infraspinatus syndrome because only the infraspinatus is affected. Large rotator cuff tears can also cause a suprascapular neuropathy because the medially retracted muscle belly places a traction force on the nerve [3,4].

Less commonly, suprascapular neuropathy may result from shoulder girdle trauma or from iatrogenic injury as a complication of surgery. Three-dimensional mapping of operatively treated scapular fractures has shown extension of the fracture to the spinoglenoid notch in 22% of patients [5].

FIGURE 20.1 Posterior view of the scapula demonstrating the course of the suprascapular nerve through the suprascapular and spinoglenoid notches.

Symptoms

A range of symptoms may be associated with suprascapular neuropathy. Patients' complaints are often similar to those of patients with other pathologic processes about the shoulder, including pain, weakness, and functional impairment. Some patients, however, may present only after recognizing painless atrophy. Suprascapular neuropathy is therefore difficult to diagnose on the basis of history alone. The pain, when it is present, can be poorly localized but is often located along the posterolateral shoulder and described as a deep, dull ache. This pain pattern coincides with the diffuse sensory contribution of the suprascapular nerve, as it carries sensory afferents from up to 70% of the shoulder [6]. For nontraumatic injuries, the onset is typically insidious and night pain is variable. Although it is less common, trauma can cause suprascapular neuropathy, and in this case, symptom onset is rapid.

For athletes, overhead sport-specific motions can intensify typical pain symptoms, and a decline in throwing velocity or hitting speed may be seen. Weakness is often described as a sense of fatigue during these activities.

Physical Examination

A complete physical examination of the shoulder is critical to identify a suprascapular nerve lesion and its underlying cause. Inspection may demonstrate atrophy in the supraspinatus or infraspinatus fossa. Atrophy of the supraspinatus may be difficult to visualize, given the bulk of the overlying trapezius. Isolated atrophy of the infraspinatus suggests compression of the nerve at the spinoglenoid notch. Palpation may elicit tenderness along the course of the nerve, particularly at the level of the suprascapular notch, within the supraspinous fossa or at the spinoglenoid notch. The tenderness may be enhanced with horizontal shoulder adduction, which tightens the spinoglenoid ligament. Strength testing may demonstrate weakness in abduction or external rotation. Weakness may be subtle because of compensatory muscle action. Other special tests should be performed to evaluate for labral disease, given its association with spinoglenoid notch cysts that can compress the suprascapular nerve. The examiner should also perform a thorough upper extremity neurovascular examination and evaluate the contralateral shoulder and cervical spine.

Functional Limitations

Functional limitations will vary significantly, depending on the patient's activity level. As previously mentioned, overhead athletes may see a decrease in their pitching or throwing velocity or overhead swing speed. Strength deficits are particularly prevalent in volleyball players, up to 68% of whom have external rotation strength deficits in their hitting arm [7]. Weakness may be subtle and have limited effect on performance because of compensatory muscle action. In those patients with a proximal neuropathy affecting both the supraspinatus and infraspinatus, functional declines, especially with overhead activities, are more apparent.

Diagnostic Studies

A thorough history and physical examination can heighten suspicion for a suprascapular neuropathy and lead to the initiation of further testing. Whereas standard shoulder radiographs are most often unremarkable, a Stryker notch view can be helpful as it allows visualization of anatomic variations at the suprascapular notch. If bone variations are suspected, three-dimensional computed tomography is helpful to further delineate the anatomy and to plan interventions. Magnetic resonance imaging allows evaluation of the suprascapular nerve along its course, demonstrating points of tethering or compression. Rotator cuff edema or atrophy may be appreciated, giving a sense of the severity or chronicity of the nerve compression. Magnetic resonance arthrography is the diagnostic test of choice for labral disease and also will identify an associated spinoglenoid notch cyst. Ultrasonography can also identify rotator cuff disease and paralabral cysts.

Electrodiagnostic studies are the "gold standard" test for confirming the diagnosis of suprascapular neuropathy and grading the injury severity. A demyelinating injury is suggested by a prolonged distal motor latency with stimulation at Erb point and recording over the supraspinatus or infraspinatus. The presence of fibrillation potentials, positive sharp waves, increased motor unit amplitude or duration and polyphasia, and decreased recruitment pattern on needle electromyography suggest the presence of an axonal injury [8].

A diagnostic suprascapular nerve block can also assist with diagnosis of this disorder. The nerve block should be performed with ultrasound or fluoroscopic guidance to ensure accuracy. Temporary resolution of the patient's symptoms in response to a suprascapular nerve block confirms the diagnosis of suprascapular neuropathy.

Differential Diagnosis

- Rotator cuff tendinopathy or tear
- Cervical radiculopathy
- Cervical disc degeneration
- Brachial plexopathy
- Subacromial impingement
- Labral disease
- Parsonage-Turner syndrome

Treatment

Initial

An appropriate workup to accurately determine the cause and location of the suprascapular nerve injury is imperative as treatment strategies will vary according to the precise location and cause of the pathologic process. In the absence of an identified space-occupying lesion, such as a paralabral cyst, the first line of treatment is nonoperative. Patients should be instructed to avoid repetitive overhead activities or other exacerbating arm positions. Nonsteroidal anti-inflammatory drugs or acetaminophen can be used for pain relief. As with most shoulder-related disease, physical therapy plays an important role in nonoperative management.

Rehabilitation

Physical therapy has been demonstrated to be particularly effective when injury to the nerve is the result of a dynamic process, such as in overhead athletes. Ferretti and coworkers successfully treated 35 of 38 (92%) competitive volleyball players with isolated atrophy of the infraspinatus, and although the atrophy remained unchanged at long-term follow-up, the patients were asymptomatic [9]. Early rehabilitation should focus on flexibility of the scapular protractors and elevators, such as the pectoralis minor and superior belly of the trapezius. Strengthening should include the scapular stabilizers, with particular attention to the rhomboideus major and minor, inferior and middle bellies of the trapezius, and serratus anterior. The rotator cuff should also be strengthened, with a focus on the external rotators. Proprioceptive exercises improve shoulder stability and neuromuscular control. The exercise program should initially avoid positions of abduction and external rotation and gradually progress to exercises that enter this range of motion as the patient's symptoms resolve. The final phase of rehabilitation should incorporate sports-specific training in preparation for return to sports. On completion of the final phase of supervised rehabilitation, the patient should be transitioned to a home exercise program to maintain the therapeutic gains.

Procedures

Procedures for management of suprascapular neuropathy typically serve a diagnostic purpose or provide temporary palliation. Suprascapular nerve blocks, as previously mentioned, can help localize the pain source. The suprascapular nerve can be blocked at the suprascapular notch or spinoglenoid notch. Because of the deep location and sensitive nature of the suprascapular nerve, image guidance (e.g., fluoroscopy or ultrasound) should be used in performing a suprascapular nerve block.

If a patient has a paralabral cyst causing suprascapular nerve compression in the spinoglenoid notch, an ultrasound-guided spinoglenoid notch cyst aspiration can be performed. However, this procedure frequently provides only temporary relief as the underlying pathologic change leading to the cyst (i.e., glenoid labral tear) is not addressed by this procedure [10]. Patients with chronic shoulder pain refractory to other treatments may respond to radiofrequency ablation of the suprascapular nerve.

Surgery

In the setting of failed nonoperative management, surgical intervention has been shown to provide effective pain relief and restoration of function in most patients [11]. Optimal surgical timing and approach are ongoing areas of debate. The goal of surgery is direct or indirect decompression of the nerve. For isolated suprascapular neuropathy, direct decompression can be achieved through open or arthroscopic means. The nerve is released at the suprascapular or spinoglenoid notch, depending on the cause. Some authors have advocated for routine release of both the transverse scapular ligament and spinoglenoid ligament to optimize the likelihood of a full neurologic recovery [12,13]. When underlying disease, such as a paralabral cyst or rotator cuff tear, is present, debate exists as to whether indirect decompression through addressing the primary pathologic process is sufficient to alleviate the neuropathy or whether concomitant direct nerve decompression is also necessary [1,12,13]. Further research is required to answer this question.

Potential Disease Complications

Ongoing compression of the suprascapular nerve could lead to permanent muscle weakness and progressive shoulder dysfunction that is usually not reversible when atrophy is significant. Given the role of the supraspinatus and infraspinatus in stabilizing the humeral head within the glenoid, one could speculate that rotator cuff arthropathy would be the end-result of long-term suprascapular neuropathy. It has been suggested that earlier surgical decompression may improve the likelihood for restoration of full muscle strength and normalization of shoulder function [11].

Potential Treatment Complications

Patients who are treated with mild oral analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs are at risk for complications associated with these medications, such as liver or renal toxicity and peptic ulcer disease. Suprascapular nerve blocks can result in direct trauma to the suprascapular nerve. The complex anatomy of the suprascapular nerve places it at risk for injury during any surgical approach. Injuries can include nerve traction and nerve laceration. Ongoing pain, continued muscle atrophy, or recurrence can occur despite attempts at treatment.

Definition

In the simplest of terms, arthritis of the elbow reflects a loss of articular cartilage in the ulnotrochlear and radiocapitellar articulations. Destruction of the articulating surfaces and bone loss or, alternatively, excess bone formation in the form of osteophytes can be present. Joint contractures are common. Joint instability can result from inflammatory or traumatic injury to the bone architecture, capsule, and ligaments. The spectrum of disease ranges from intermittent pain or loss of motion with minimal changes detectable on radiographs to the more advanced stages of arthritis with a limited, painful arc of motion and radiographic demonstration of osteophyte formation, cysts, and loss of joint space. Ultimately, these destructive processes may result in complete ankylosis or total instability of the elbow.

The major causes of elbow arthritis are the inflammatory arthropathies, of which rheumatoid arthritis is the predominant disease. Arthritis of the elbow eventually develops in approximately 20% to 50% of patients with rheumatoid arthritis [1]. Involvement of the elbow in juvenile rheumatoid arthritis is not uncommon. Other inflammatory conditions affecting the elbow joint are systemic lupus erythematosus, the seronegative spondyloarthropathies (ankylosing spondylitis, psoriatic arthritis, Reiter syndrome, and enteropathic arthritis), and crystalline arthritis (gout and pseudogout). Post-traumatic arthritis may result from intra-articular fractures of the elbow. Osteonecrosis of the capitellum or trochlea, leading to arthritis, has also been described [2,3]. Primary osteoarthritis of the elbow is a rare condition, responsible for less than 5% of elbow arthritis [4]. Interestingly, the incidence is significantly higher in the Alaskan Eskimo and Japanese populations [5]. Primary elbow arthritis usually affects the dominant arm of men in their 50s. Repetitive, strenuous arm use appears to be a risk factor; primary elbow arthritis has been reported in heavy laborers, weightlifters, and throwing athletes. Synovial chondromatosis is another rare cause of elbow arthritis [3].

Symptoms

The symptoms of elbow arthritis reflect, in part, the underlying etiology and severity of the disease process. Regardless of the etiology, however, the inability to fully straighten (extend) the elbow is a nearly universal complaint of patients with elbow arthritis. Associated symptoms of cubital tunnel syndrome (ulnar neuropathy at the elbow) include numbness in the ring and small fingers, loss of hand dexterity, and aching pain along the ulnar aspect of the forearm. Cubital tunnel syndrome is neither uncommon nor unexpected, given the proximity of the ulnar nerve to the elbow joint (see Chapter 27).

Patients with early rheumatoid involvement complain of a swollen, painful joint with morning stiffness. Progressive loss of motion or instability is seen in later stages. Compression of the posterior interosseous nerve by rheumatoid synovitis can occasionally produce the inability to extend the fingers.

Patients with crystalline arthritis of the elbow may complain of severe pain, swelling, and limited motion; an expedient evaluation is warranted to rule out a septic elbow in such cases.

Post-traumatic or idiopathic arthritis of the elbow, in contrast, usually is manifested with painful loss of motion without the significant effusions, warmth, or constant pain associated with an inflamed synovium. These patients usually complain of pain at the extremes of motion secondary to osteophyte impingement, and they typically have more trouble extending the elbow than flexing it. Pain throughout the arc of motion implies advanced arthritis. The final stages of arthritis, irrespective of cause, can include complaints of severe pain and decreased motion that hinder activities of daily living as well as the cosmetic deformity of the flexed elbow posture.

Physical Examination

Physical examination findings vary according to the cause and stage of the elbow arthritis. A flexion contracture is almost always present. The range of motion should be monitored at the initial examination and at subsequent follow-up examinations.

Normal adult elbow range of motion in extension-flexion is from 0 degrees to about 150 degrees; pronation averages 75 degrees, and supination averages 85 degrees. A functional range of motion is considered to be 30 to 130 degrees, with 50 degrees of both pronation and supination [6].

All other joints should be assessed as well. Strength should be normal but may be impaired in long-standing elbow arthritis because of disuse or, in more acute cases, pain. Weakness may also be noted in the presence of associated neuropathies. In the absence of associated neuropathies, deep tendon reflexes and sensation should be normal.

Associated ulnar nerve irritation can produce a sensitive nerve with the presence of Tinel sign over the cubital tunnel, diminished sensation in the small finger and ulnar half of the ring finger, and weakness of the intrinsic muscles (see Chapter 27). Numbness provoked by acute flexion of the elbow for 30 to 60 seconds is a positive elbow flexion test result.

Effusions, synovial thickenings, and erythema are commonly noted in the inflammatory arthropathies during acute flares. Loss of motion in flexion and extension as well as in

pronation and supination can be present because the synovitis affects all articulating surfaces in the elbow. Pain, limited motion, and crepitus worsen as the disease progresses. On occasion, rheumatoid destruction of the elbow will produce instability, which may be perceived by the patient as weakness or mechanical symptoms. Examination of such elbows will demonstrate laxity to varus and valgus stress; posterior instability may also be seen.

In contrast, progressive primary or post-traumatic arthritis of the elbow results in stiffness. The loss of extension is usually worse than the loss of flexion. Pain is present with forced extension or flexion. Crepitus may be palpable throughout the arc of flexion-extension or with forearm rotation.

Functional Limitations

The elbow functions to position the hand in space. Significant loss of extension can hinder an individual's ability to interact with the environment, making activities that require nearly full extension, like carrying groceries or briefcases, painful. Significant loss of flexion can interfere with activities of daily living such as eating, shaving, and washing. A normal shoulder can compensate well for a lack of pronation, whereas a normal shoulder, wrist, and cervical spine can compensate, albeit awkwardly, for a lack of full elbow flexion. There is no simple solution for a significant lack of elbow extension; the body must be moved closer to the desired object. Compensatory mechanisms are often impaired in patients with rheumatoid arthritis, magnifying the impact of the elbow arthritis on function.

Diagnostic Studies

Anteroposterior, lateral, and oblique radiographic views of the elbow are usually sufficient for diagnosis of elbow arthritis. The radiographs should be inspected for joint space narrowing, osteophyte and cyst formation, and bone destruction. For the rheumatoid patient, the Mayo Clinic radiographic classification of rheumatoid involvement is useful (Table 21.1) [7]. Dramatic loss of bone is evident as the disease progresses (Fig. 21.1). This pattern of destruction is not seen, however, in the post-traumatic or idiopathic patient. Radiographic features in these patients include spurs or osteophytes on the coronoid and olecranon, loose bodies, and narrowing of the coronoid and olecranon fossae (Fig. 21.2).

Magnetic resonance arthrography or computed tomographic arthrography may help localize suspected loose bodies. Magnetic resonance imaging is most valuable for confirmation of suspected osteonecrosis.

Table 21.1 Radiographic Classification of Rheumatoid Arthritis [7]

I	Synovitis with a normal-appearing joint
II	Loss of joint space but maintenance of the subchondral architecture
IIIa	Alteration of the subchondral architecture
IIIb	Alteration of the architecture with deformity
IV	Gross deformity

FIGURE 21.1 Rheumatoid arthritis. Anteroposterior (A) and lateral (B) elbow radiographs of a 40-year-old woman with long-standing elbow pain. Osteopenia and symmetric joint space narrowing are present. The lateral radiograph demonstrates early bone loss in the ulna. This is categorized as stage IIIa.

FIGURE 21.2 Primary degenerative elbow arthritis. Anteroposterior (A) and lateral (B) elbow radiographs of a 52-year-old man with dominant right elbow pain at the extremes of motion. A, Joint space narrowing and obliteration of the coronoid fossa. B, Coronoid and olecranon spurs and a large anterior loose body are evident.

The diagnosis of rheumatoid arthritis will have already been made in the majority of patients who present with rheumatoid elbow involvement. When isolated inflammatory arthritis of the elbow is suspected, appropriate serologic studies may include analysis of rheumatoid factor, antinuclear antibody, HLA-B27, and erythrocyte sedimentation rate. Elbow aspiration may be needed to rule out a crystal-line or infectious cause in patients who present with a warm, stiff, swollen, and painful joint with no history of trauma or inflammatory arthritis.

Differential Diagnosis

- Medial or lateral epicondylitis
- Median nerve compression
- Elbow instability
- Radial tunnel syndrome
- Septic arthritis
- Cervical radiculopathy
- Acute fracture
- Elbow contracture
- Cubital tunnel syndrome

Treatment

Initial

Treatment of elbow arthritis depends on the diagnosis, degree of involvement, functional limitations, and pain. When the elbow is one of a number of joints actively involved with inflammatory arthritis, the obvious treatment is systemic. Disease-modifying agents have had a dramatic effect in relieving symptoms and retarding the progression of arthritis for many of these patients. For systemic disease, a rheumatology consultation can be beneficial.

The initial local treatment of an acutely inflamed elbow joint includes rest. A simple sling places the elbow in a relatively comfortable position. The patient should be encouraged to remove the sling for gentle range of motion exercises of the elbow and shoulder several times daily. Icing of the elbow for 15 minutes several times a day for the first few days may be beneficial.

Nonoperative treatment of primary osteoarthritis of the elbow primarily consists of rest, activity modification, and nonsteroidal anti-inflammatory drugs. Oral analgesics may help with pain control. Topical treatments such as capsaicin can be tried as well.

Patients who have associated cubital tunnel symptoms are instructed to avoid direct pressure over the elbow and to avoid prolonged elbow flexion. A static night splint that maintains the elbow in about 30 degrees of flexion may help alleviate cubital tunnel symptoms (see Chapter 27).

Rehabilitation

Once the acute inflammation has subsided, physical or occupational therapy may be instituted to regain elbow motion and strength and to educate the patient in activity modification and pain control measures.

Therapy should focus on improving range of motion and strength throughout the upper body with a goal of improving function regardless of the degree of elbow arthritis. Adaptive equipment, such as reachers, can be recommended. Ergonomic workstation equipment may also be useful (e.g., voice-activated computer software, forearm rests).

Modalities such as ultrasound and iontophoresis may help with pain control.

Nighttime static, static-progressive, or dynamic extension splinting may be indicated to relieve significant elbow contractures. Braces may be effective in the setting of instability. The goal of therapy is *functional* rather than full elbow motion.

In primary osteoarthritis of the elbow, corrective splinting is not indicated because bone impingement is usually present. Similarly, therapy may actually aggravate the symptoms and should be ordered judiciously.

Rehabilitation is critical to the success of surgical procedures around the elbow. The rheumatoid patient commonly has multiple joint problems that must not be neglected during treatment of the elbow. The shoulder is at particular risk for stiffness. A good operation, a motivated patient, and a knowledgeable and skillful therapist are necessary to optimize postoperative results. Postoperative rehabilitation depends on the procedure and the surgeon's preference. However, in general, physical or occupational

therapy should be recommended to restore range of motion and strength.

Procedures

For recalcitrant symptoms, intra-articular steroid injections are effective in relieving the pain associated with synovitis (Fig. 21.3).

The elbow joint is best accessed through the "soft spot," the center of the triangle formed by the lateral epicondyle, the tip of the olecranon, and the radial head. The patient is placed with the elbow between 50 and 90 degrees of flexion. For the posterolateral approach, the lateral epicondyle and the posterior olecranon are palpated. Under sterile conditions, with use of a 25-gauge, 1½-inch needle, 3 to 4 mL of an anesthetic-corticosteroid mixture (e.g., 1 mL of 80 mg/mL methylprednisolone and 3 mL of 1% lidocaine) is injected. The needle is directed proximally toward the head of the radius and medially into the elbow joint. No resistance should be noted as the needle enters the joint. If an effusion is present, aspiration may be done before the anesthetic-corticosteroid mixture is injected.

For the posterior approach, the olecranon fossa is palpated just proximal to the tip of the olecranon. The needle is then inserted above the superior aspect of and lateral to the olecranon. Again, it should enter the joint without resistance.

Postinjection care may include icing of the elbow for 10 to 20 minutes after the injection and then two or three times daily thereafter. The patient should be informed that the pain may worsen for the first 24 to 36 hours and that the medication may take 1 week to work.

In general, repeated injections are not recommended. Although the intra-articular steroids are effective in treating synovitis, they also temporarily inhibit chondrocyte synthesis, an effect that could potentially accelerate arthritis.

Surgery

Patients who have failed to respond to treatment after 3 to 6 months of adequate medical therapy are potential candidates for surgery. Refractory pain is the best indication for surgery. In assessment of the surgical candidate with primary elbow arthritis, it is important to listen carefully to the patient's complaints. Many patients are dissatisfied with the simple fact that they cannot fully straighten the elbow. Such patients will not be fully satisfied with surgery.

Intermittent locking or catching, suggestive of a loose body, is often best treated with arthroscopy. Pain at the extremes of motion is consistent with olecranon and coronoid osteophyte impingement. An ulnohumeral arthroplasty, or surgical débridement of the elbow joint, may be recommended. Traditionally, open surgical techniques have been performed to remove impinging osteophytes. More recent arthroscopic advances have permitted this débridement to be performed in a less invasive manner, with potentially less morbidity. However, arthroscopic treatment of elbow contractures is a technically demanding procedure [8]. Ulnohumeral arthroplasty is successful at achieving its principal goal—pain relief at the extremes of motion. However, it is only marginally successful at actually improving motion, with an average improvement in extension of 7 to 12 degrees and an average improvement in flexion of 8 to 17 degrees in

FIGURE 21.3 Internal anatomic (A) and approximate surface anatomic (B, lateral; C, posterior) sites for injection of the elbow laterally and posteriorly. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

four reported series [4,9–11]. Overall, 85% of patients in these series were satisfied with the results. As expected, the results deteriorate with time as the arthritis progresses.

Less commonly, patients with primary arthritis complain of pain throughout the arc of motion. Their radiographs will probably demonstrate advanced arthritis with severe joint space narrowing. Simple removal of the osteophytes is not likely to be successful. Total elbow arthroplasty would seem to be a reasonable option. However, unlike their rheumatoid counterparts, most of these patients are otherwise healthy, vigorous people who would regularly stress their joint replacement. For this reason, total elbow arthroplasty in this setting is best reserved for the sedentary patient older than 65 years [12].

For the younger patient with advanced primary arthritis, a distraction interposition arthroplasty is recommended [13–15]. This procedure involves a radical débridement of the joint followed by a resurfacing of the joint surfaces with an interposition material, such as autologous fascia

lata or allograft Achilles tendon. A hinged external fixator is then applied, which will protect the healing interposition material while simultaneously maintaining elbow stability and permitting motion. In the one relatively large series of distraction interposition arthroplasty [15], pain relief was satisfactory in 69% of patients at an average of 5 years postoperatively. An advantage of interposition arthroplasty is the potential for conversion to total elbow arthroplasty, ideally after the age of 60 years [16], but this procedure certainly does not produce a normal elbow.

Other nonimplant surgical options include elbow arthrodesis and resection arthroplasty. There is no ideal position for an elbow fusion. The elbow looks more cosmetically appealing when it is relatively straight. However, this position is relatively useless. Consequently, elbow arthrodesis is performed rarely, usually in the setting of intractable infection. Resection arthroplasty is an option for a failed total elbow arthroplasty. This procedure permits some elbow motion, although the elbow tends to be very unstable.

For the rheumatoid patient with elbow arthritis, elbow synovectomy and débridement provide predictable short-term pain relief [17]. Interestingly, the results do not necessarily correlate with the severity of the arthritis. The results do, however, deteriorate somewhat over time, drifting down from 90% success at 3 years to 70% success by 10 years as the synovitis recurs [18–20]. Elbow motion is not necessarily improved by synovectomy; only 40% of patients obtain better motion. A study comparing arthroscopic and open synovectomy demonstrated equivalent results with either technique if the preoperative arc of flexion is greater than 90 degrees [19]. For stiff rheumatoid elbows, arthroscopic synovectomy performed better than the open method did.

Total elbow arthroplasty is a reliable procedure for the rheumatoid patient with advanced elbow arthritis [21,22]. The Mayo Clinic has reported excellent results with a semi-constrained prosthesis [23], with pain relief in 92% of patients and an average arc of motion of 26 to 130 degrees, with 64 degrees of pronation and 62 degrees of supination. An outcomes study demonstrated good satisfaction of the patients, although the majority of patients continued to have some functional impairments, presumably due, in part, to rheumatoid involvement in other joints [24]. In spite of the excellent clinical results, the patient should be made aware that the complication rate for total elbow arthroplasty is significantly higher than that for the more conventional hip and knee replacements.

Potential Disease Complications

End-stage rheumatoid arthritis of the elbow can produce either severe stiffness or instability. Advanced primary arthritis invariably produces stiffness. Either outcome results in pain and limited function of the involved extremity. In addition, entrapment or traction neuritis of the ulnar nerve is not uncommon. Compressive injury to the posterior interosseous nerve from rheumatoid synovial hyperplasia has also been reported.

Potential Treatment Complications

The systemic complications of the disease-modifying agents used in treatment of rheumatoid arthritis are numerous and are beyond the scope of this chapter (see Chapters 34 and 41). Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Intra-articular steroid injections introduce the risk of iatrogenic infection and may produce transient chondrocyte damage.

Potential surgical complications include infection, wound problems, neurovascular injury, stiffness, recurrent synovitis, triceps disruption, periprosthetic lucency, fracture, and iatrogenic instability. In the primary and post-traumatic osteoarthritic elbow, motion-improving procedures such as ulnohumeral arthroplasty do not halt the inevitable radiographic progression of the disease. Similarly, synovectomy of the rheumatoid elbow, even if it is successful in alleviating pain and synovitis, does not reliably prevent further joint destruction. Preoperative ulnar nerve symptoms can occasionally be made worse by surgery, and simultaneous ulnar nerve transposition should be considered in such patients when the preoperative range of motion is limited [11]. In an analysis of 473 consecutive elbow arthroscopies, major and temporary minor complications occurred in 0.8% and

11% of patients, respectively [8]. The most significant risk factors for development of temporary nerve palsies were rheumatoid arthritis and contracture.

With total elbow arthroplasty, wound healing problems, infection, triceps insufficiency, and implant loosening are the principal complications, occurring in approximately 5% to 7% of patients. As a result, most surgeons place lifelong restrictions on high-impact loading (no golf, no lifting of more than 10 pounds) to minimize the need for revision surgery.

Synonyms

Tendinosis [1]
Lateral epicondylitis
Tennis elbow

ICD-9 Code

726.32 Lateral epicondylitis

ICD-10 Codes

M77.10 Lateral epicondylitis, unspecified elbow
M77.11 Lateral epicondylitis, right elbow
M77.12 Lateral epicondylitis, left elbow

Definition

Epicondylitis is a general term used to describe inflammation, pain, or tenderness in the region of the medial or lateral epicondyle of the humerus. The actual nidus of pain and pathologic change has been debated. Lateral epicondylitis implies an inflammatory lesion with degeneration at the tendinous origin of the extensor muscles (the lateral epicondyle of the humerus). The tendon of the extensor carpi radialis brevis muscle is primarily affected. Other muscles that can contribute to the condition are the extensor carpi radialis longus and the extensor digitorum communis.

Although the term *epicondylitis* implies an inflammatory process, inflammatory cells are not identified histologically. Instead, the condition may be secondary to failure of the musculotendinous attachment with resultant fibroplasia [2], termed tendinosis. Other postulated primary lesions include angiofibroblastic tendinosis, periostitis, and enthesitis [3]. Overall, the focus of injury appears to be the common extensor tendon origin. Symptoms may be related to failure of the repair process [4].

Repetitive stress has been implicated as a factor in this condition [5]. Overuse from a tennis backhand (especially a one-handed backhand with poor technique) can frequently lead to lateral epicondylitis (hence, the term *tennis elbow* is frequently used synonymously with lateral epicondylitis, regardless of its etiology). Repetitive computer use (especially with a mouse) as well as golf, swimming, and baseball can cause or exacerbate epicondylitis.

Symptoms

Patients usually report pain in the area just distal to the lateral epicondyle. The patient may complain of pain radiating proximally or distally. Patients may also complain of pain with wrist or hand movement, such as gripping a doorknob, carrying a briefcase, or shaking hands. Patients occasionally report swelling as well.

Physical Examination

On examination, the hallmark of epicondylitis is tenderness over the extensor muscle origin. The common origin of the extensor muscles can be located one fingerbreadth below the lateral epicondyle. With lateral epicondylitis, pain is increased with resisted wrist extension, especially with the elbow extended, the forearm pronated, the wrist radially deviated, and the hand in a fist. The middle finger test can also be used to assess for lateral epicondylitis. Here, the proximal interphalangeal joint of the long finger is resisted in extension, and pain is elicited over the lateral epicondyle. Swelling is occasionally present. In cases of recalcitrant lateral epicondylitis, the diagnosis of radial nerve entrapment should be considered. The radial nerve can become entrapped just distal to the lateral epicondyle where the nerve pierces the intermuscular septum (between the brachialis and brachioradialis muscles). There may be localized tenderness along the course of the radial nerve around the radial head. Motor and sensory findings are usually absent.

Functional Limitations

The patient may complain of an inability to lift or to carry objects on the affected side secondary to increased pain. Typing, using a computer mouse, or working on a keyboard may re-create the pain. Even handshaking or squeezing may be painful in lateral epicondylitis. Athletic activities may

cause pain, especially with an acute increase in repetition, poor technique, and equipment changes (frequently with a new racket or stringing).

Diagnostic Studies

The diagnosis is usually made on clinical grounds. Magnetic resonance imaging, which is particularly useful for soft tissue definition, can be used to assess for tendinitis, tendinosis, degeneration, partial tears or complete tears, and detachment of the common extensor tendons at the lateral epicondyle [6]. Magnetic resonance imaging is rarely needed, however, except in recalcitrant epicondylitis, and it will not alter the treatment significantly in the early stages. The lateral collateral ligament complexes can be evaluated for tears as well as for chronic degeneration and scarring. Ultrasonography has been used to diagnose lateral epicondylitis [7]. Arthrography may be beneficial if capsular defects and associated ligament injuries are suspected. Barring evidence of trauma, early radiographs are of little help in this condition but may be useful in cases of resistant tendinitis and to rule out occult fractures, arthritis, and an osteochondral loose body.

Differential Diagnosis

Posterior interosseous nerve syndrome
 Bone infection or tumors
 Ulnar or median neuropathy around the elbow
 Osteoarthritis
 Acute calcification around the lateral epicondyle [8]
 Osteochondral loose body
 Anconeus compartment syndrome [9]
 Triceps tendinitis
 Degenerative arthrosis [10]
 Elbow synovitis
 Lateral ligament instability [11]
 Radial head fracture
 Bursitis
 Collateral ligament tears
 Hypertrophic synovial plica [12]

Treatment

Initial

Initial treatment consists of relative rest, avoidance of repetitive motions involving the wrist, activity modification to avoid stress on the epicondyle, anti-inflammatory medications, and thermal modalities such as heat and ice for acute pain. Patients who develop lateral epicondylitis from tennis should modify their stroke (especially improving the backhand stroke to ensure that the forearm is in midpronation and the trunk is leaning forward) and their equipment, usually by reducing string tension and enlarging the grip size [5]. Frequently, a two-handed backhand will relieve the stress sufficiently.

In addition, a forearm band (counterforce brace) worn distal to the extensor muscle group origin can be beneficial (Fig. 22.1). The theory behind this device is that it will dissipate forces over a larger area of tissue than the lateral attachment site. Alternatively, the use of wrist immobilization splints may be helpful. A splint set in neutral can be helpful

FIGURE 22.1 Forearm band (counterforce brace) used in patients with lateral epicondylitis.

for lateral epicondylitis by relieving the tension on the flexors and extensors of the wrist and fingers. A splint set in 30 to 40 degrees of wrist extension will relieve the tension on the extensor tendons, including the extensor carpi radialis brevis muscle as well as other wrist and finger extensors [13,14]. Dynamic extension bracing has also been proposed [15].

Rehabilitation

Rehabilitation may include physical or occupational therapy. Therapy should include two phases. The first phase is directed at decreasing pain by physical modalities (ultrasound, electrical stimulation, phonophoresis, cortisone iontophoresis [16], myofascial release [17], heat, ice, massage) and decreasing disability (education, reduction of repetitive stress, and preservation of motion). When the patient is pain free, a gradual program is implemented to improve strength and endurance of wrist extensors and stretching. This program must be carefully monitored to permit strengthening of the muscles and work hardening of the tissues without itself causing an overuse situation. The patient should start with static exercises and advance to progressive resistive exercises (with an emphasis on the eccentric phase of the exercise). Thera-Band, light weights, and manual (self) resistance exercises can be used.

Work or activity restrictions or modifications may be required for a time.

Procedures

Injection of corticosteroid, usually with a local anesthetic, into the area of maximum tenderness (approximately 1 to 5 cm distal to the lateral epicondyle) has been shown to be effective in treatment of lateral epicondylitis (Fig. 22.2) [18]. To confirm the diagnosis, a trial of lidocaine alone may be given. An immediate improvement in grip strength should be noted after injection. Postinjection treatment includes icing of the affected area both immediately (for 5 to 10 minutes) and thereafter (a reasonable regimen is 20 minutes two or three times per day for 2 weeks) and wearing of a wrist splint (particularly for activities that involve wrist movement). The wrist splint should be set in slight extension for lateral

FIGURE 22.2 Under sterile conditions, with use of a 27-gauge needle and 1 to 2 mL of a local anesthetic combined with 1 to 2 mL of a corticosteroid preparation, inject the solution approximately 1 to 5 cm distal to the lateral epicondyle. The injected materials should flow smoothly. Resistance generally indicates that the solution is being injected directly into the tendon, and this should be avoided.

epicondylitis. Exacerbating activities are to be avoided. Platelet-rich plasma injections have been shown to reduce pain and to increase function in patients with lateral epicondylitis [19–21]. Injection of botulinum toxin into the extensor digitorum communis muscles to the third and fourth digits has been reported to be beneficial in chronic treatment-resistant lateral epicondylitis [22,23].

There are studies that support acupuncture as an effective modality in the short-term relief of lateral epicondylitis [24–26]. Extracorporeal shock wave treatment may also be beneficial in lateral epicondylitis [27].

Surgery

Surgery may be indicated in those patients with continued severe symptoms who do not respond to conservative management. For lateral epicondylitis, surgery is aimed at excision and revitalization of the pathologic tissue in the extensor carpi radialis brevis and release of the muscle origin [28]. Pinning may be done if the elbow joint is unstable [29].

Potential Disease Complications

Possible long-term complications of untreated epicondylitis include chronic pain, loss of function, and possible elbow contracture. In general, epicondylitis is more easily and successfully treated in the acute phase.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Local steroid injections may increase the risk for disruption of tissue planes, create high-pressure tissue necrosis, rupture tendons [1], damage nerves, promote skin depigmentation or atrophy, or cause infection [30].

CHAPTER 23

Medial Epicondylitis

Lyn D. Weiss, MD

Jay M. Weiss, MD

Synonyms

Tendinosis [1]
Medial epicondylitis
Pitcher's elbow
Little Leaguer's elbow
Golfer's elbow

ICD-9 Code

726.31 Medial epicondylitis

ICD-10 Codes

M77.00 Medial epicondylitis, unspecified elbow
M77.01 Medial epicondylitis, right elbow
M77.02 Medial epicondylitis, left elbow

Definition

Epicondylitis is a general term used to describe inflammation, pain, or tenderness in the region of the medial or lateral epicondyle of the humerus. The actual nidus of pain and pathologic change has been debated. Medial epicondylitis implies an inflammatory lesion with degeneration at the origin of the flexor muscles (the medial epicondyle of the humerus). In medial epicondylitis, the tendon of the flexor muscle group is affected (flexor carpi radialis, flexor carpi ulnaris, flexor digitorum superficialis, and palmaris longus).

Although the term *epicondylitis* implies an inflammatory process, inflammatory cells are not identified histologically. Instead, the condition may be secondary to failure of the musculotendinous attachment with resultant fibroplasia [2], termed tendinosis. Other postulated primary lesions include angiofibroblastic tendinosis, periositis, and enthesitis [3]. In children, medial elbow pain may result from repetitive stress on the apophysis of the medial epicondyle ossification center (Little Leaguer's elbow) [4]. Overall, the focus of injury appears to be the

muscle origin. Symptoms may be related to failure of the repair process [5].

Repetitive stress has been implicated as a factor in this condition [6]. Poor throwing mechanics and excessive throwing have been implicated in Little Leaguer's elbow. Repetitive wrist flexion, as in the trailing arm in a golf swing, can cause medial epicondylitis (hence, the term *golfer's elbow* is frequently used for medial epicondylitis, regardless of etiology).

Symptoms

Patients usually report pain in the area just distal to the medial epicondyle. The patient may complain of pain radiating proximally or distally. Patients may also complain of pain with wrist or hand movement, such as gripping a doorknob, carrying a briefcase, or shaking hands. Patients occasionally report swelling as well.

Physical Examination

On examination, the hallmark of epicondylitis is tenderness over the flexor muscle origin (medial epicondylitis). The origin of the flexor muscles can be located one fingerbreadth below the medial epicondyle. With medial epicondylitis, pain is increased with resisted wrist flexion. There may be localized tenderness along the course of the radial nerve around the radial head. Motor and sensory findings are usually absent.

Functional Limitations

The patient may complain of an inability to lift or to carry objects on the affected side secondary to increased pain. Typing, using a computer mouse, or working on a keyboard may re-create the pain. Even handshaking or hand squeezing may be painful in medial epicondylitis. Athletic activities may cause pain, especially with an acute increase in repetition, poor technique, and equipment changes.

Diagnostic Studies

The diagnosis is usually made on clinical grounds. Magnetic resonance imaging, which is particularly useful for soft tissue definition, can be used to assess for tendinitis, tendinosis, degeneration, partial tears or complete tears, and detachment of the common flexor at the medial epicondyles [7]. Magnetic

resonance imaging is rarely needed, however, except in recalcitrant epicondylitis, and it will not alter the treatment significantly in the early stages. The medial collateral ligament complexes can be evaluated for tears as well as for chronic degeneration and scarring. Ultrasonography has been used to diagnose medial epicondylitis [8,9]. Arthrography may be beneficial if capsular defects and associated ligament injuries are suspected. Barring evidence of trauma, early radiographs are of little help in this condition but may be useful in cases of resistant tendinitis and to rule out occult fractures, arthritis, and osteochondral loose body. Early radiographic studies (before commencing a rehabilitation program) may be considered in skeletally immature children with elbow pain to rule out growth plate disorders, osteochondritis dissecans, or ulnar collateral ligament tears [10].

Differential Diagnosis

Posterior interosseous nerve syndrome
 Bone infection or tumors
 Ulnar neuropathy around the elbow
 Osteoarthritis
 Osteochondral loose body
 Anconeus compartment syndrome [11]
 Triceps tendinitis
 Degenerative arthrosis [12]
 Elbow synovitis
 Medial ligament instability [13]
 Radial head fracture
 Bursitis
 Collateral ligament tears
 Hypertrophic synovial plica [14]

Treatment

Initial

Initial treatment consists of relative rest, avoidance of repetitive motions involving the wrist, activity modification to avoid stress on the epicondyle, anti-inflammatory medications, and thermal modalities such as heat and ice for acute pain. Patients who develop medial epicondylitis from golf should consider modifying their swing to avoid excessive force on wrist flexor muscles. Biomechanical modifications may help reduce symptoms if the medial epicondylitis is thought to be due to poor pitching technique.

In addition, a forearm band (counterforce brace) worn distal to the flexor muscle group origin can be beneficial. The theory behind this device is that it will dissipate forces over a larger area of tissue than the medial attachment site [15]. Alternatively, the use of wrist immobilization splints may be helpful. A splint set in neutral can be helpful for medial epicondylitis by relieving the tension on the flexors and extensors of the wrist and fingers. Dynamic extension bracing has also been proposed [16].

Rehabilitation

Rehabilitation may include physical or occupational therapy. Therapy should include two phases. The first phase is directed at decreasing pain by physical modalities

(ultrasound, electrical stimulation, phonophoresis, heat, ice, massage) and decreasing disability (education, reduction of repetitive stress, and preservation of motion). When the patient is pain free, a gradual program is implemented to improve strength and endurance of wrist flexors and should include stretching. This program must be carefully monitored to permit strengthening of the muscles and work hardening of the tissues without itself causing an overuse situation. The patient should start with static exercises and advance to progressive resistive exercises. Thera-Band, light weights, Kinesio taping [17], and manual (self) resistance exercises can be used.

Work or activity restrictions or modifications may be required for a time.

Procedures

Injection of corticosteroid, usually with a local anesthetic, into the area of maximum tenderness (approximately 1 to 5 cm distal to the medial epicondyle) has been shown to be effective in treatment of epicondylitis (Fig. 23.1) [18,19]. To confirm the diagnosis, a trial of lidocaine alone may be given. An immediate improvement in grip strength should be noted after injection. Postinjection treatment includes icing of the affected area both immediately (for 5 to 10 minutes) and thereafter (a reasonable regimen is 20 minutes two or three times per day for 2 weeks) and wearing of a wrist splint (particularly for activities that involve wrist movement). The wrist splint should be set in neutral for medial epicondylitis. Exacerbating activities are to be avoided. Platelet-rich plasma injections have been shown to reduce pain and to increase function in patients with recalcitrant epicondylitis [20], as have botulinum toxin injections [21].

Injections for medial epicondylitis must be used cautiously because of the risk of injury to the ulnar nerve (either by direct injection or by tissue changes that may promote nerve injury).

Surgery

Surgery may be indicated in those patients with continued severe symptoms who do not respond to conservative management. Surgery is aimed at excision and revitalization of the pathologic tissue and release of the muscle origin [22]. Pinning may be done if the elbow joint is unstable [4].

FIGURE 23.1 Medial epicondylitis injection.

Potential Disease Complications

Possible long-term complications of untreated epicondylitis include chronic pain, loss of function, and possible elbow contracture. Medial epicondylitis may lead to reversible impairment (neurapraxia) of the ulnar nerve [23]. In general, epicondylitis is more easily and successfully treated in the acute phase.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Local steroid injections may increase the risk for disruption of tissue planes, create high-pressure tissue necrosis, rupture tendons [1], damage nerves, promote skin depigmentation or atrophy, or cause infection [24].

ICD-9 Code

354.1 Other lesion of median nerve (median nerve neuritis)

ICD-10 Codes

G56.10 Other lesion of median nerve, unspecified upper limb
G56.11 Other lesion of median nerve, right upper limb
G56.12 Other lesion of median nerve, procedure upper limb

Definition

There are three general areas in which the median nerve can become entrapped around the elbow and forearm. Because this chapter mainly deals with entrapment below the elbow and above the wrist, the most proximal and least frequent entrapment is not discussed but merely mentioned. Elbow median nerve entrapment is the compression of the nerve by a dense band of connective tissue called the ligament of Struthers, an aberrant ligament found immediately above the elbow. The topics discussed in this chapter are compression of the median nerve at or immediately below the elbow, where the pronator teres muscle compresses it, and compression distally of a branch of the median nerve—the anterior interosseous nerve.

Increased risk for pronator syndrome may be associated with individuals involved in repetitive elbow, wrist, and hand movements, such as chopping wood, playing racket

sports, rowing, weightlifting, and throwing. However, pronator syndrome is four times more likely to affect women than men, suggesting that the dominant risk factor is an anatomic anomaly (structural variation) and not overuse. The dominant arm is most likely to be affected, particularly if the individual is heavily muscled (muscle hypertrophy). Pronator syndrome is most commonly diagnosed in individuals between the ages of 40 and 50 years [1]. Pronator syndrome is rare but is the second most common cause of medial nerve compression after carpal tunnel syndrome. Pronator syndrome is responsible for less than 1% of all median nerve entrapment disorders [2]. Anterior interosseous syndrome has a similar 1% occurrence rate in median nerve entrapment disorders [3].

Pronator Teres Syndrome

Pronator teres syndrome [4,5] is a symptom complex that is produced where the median nerve crosses the elbow and becomes entrapped as it passes first beneath the lacertus fibrosus—a thick fascial band extending from the biceps tendon to the forearm fascia—then between the two heads (superficial and deep) of the pronator teres muscle and under the edge of the flexor digitorum sublimis (Fig. 24.1). Compression may be related to a local process, such as pronator teres hypertrophy, tenosynovitis, muscle hemorrhage, fascial tear, postoperative scarring, anomalous median artery, or giant lipoma. The median nerve may also be injured by occupational strain, such as carrying a grocery bag or guitar playing, and by insertion of a catheter [4–13].

Anterior Interosseous Syndrome

The anterior interosseous nerve arises from the median nerve 5 to 8 cm distal to the lateral epicondyle [4,6,14]. Slightly distal to its course through the pronator teres muscle, the median nerve gives off the anterior interosseous nerve, a purely motor branch (Fig. 24.2). It contains no fibers of superficial sensation but does supply deep pain and proprioception to some deep tissues, including the wrist joint. This nerve may be damaged by direct trauma, forearm fractures, humeral fracture, injection into or blood drawing from the cubital vein, supracondylar fracture, and fibrous bands related to the flexor digitorum sublimis and flexor digitorum profundus muscles. In some patients, it is a component of brachial amyotrophy of the shoulder girdle (proximal fascicular lesion) or related to cytomegalovirus

FIGURE 24.1 The median nerve is shown descending beneath the sublimis bridge after traversing the space between the two heads of the pronator teres. The nerve is compressed at the sublimis bridge. (From Kopell HP, Thompson WA. Pronator syndrome: a confirmed case and its diagnosis. *N Engl J Med* 1958;259:713-715.)

infection or a bronchogenic carcinoma metastasis. The nerve may be partially involved, but in a fully established syndrome, three muscles are weak: flexor pollicis longus, flexor digitorum profundus to the second and sometimes the third digit, and pronator quadratus [4,6,12–18].

Symptoms

Pronator Teres Syndrome

In an acute compression, with unmistakable symptoms, the diagnosis is relatively simple to establish [5,14]. In many cases of intermittent, mild, or partial compression, the signs and symptoms are vague and nondescript. The most common symptom is mild to moderate aching pain in the proximal forearm, sometimes described as tiredness and heaviness. Use of the arm may cause a mild or dull aching pain to become deep or sharp. Repetitive elbow motions are likely to provoke symptoms. As the pain intensifies, it may radiate proximally to the elbow or even to the shoulder. Paresthesias in the distribution of the median nerve may be reported, but they are generally not as severe or well localized as the complaints in carpal tunnel syndrome. When numbness is a prominent symptom, the complaints may mimic carpal tunnel syndrome. However, unlike carpal tunnel syndrome, pronator teres syndrome rarely has nocturnal exacerbation, and the symptoms are not affected by a change of wrist position.

FIGURE 24.2 Course of the median nerve and its anterior interosseous branch.

Anterior Interosseous Syndrome

The onset of anterior interosseous syndrome can be related to exertion, or it may be spontaneous. In classic cases of spontaneous anterior interosseous nerve paralysis, there is acute pain in the proximal forearm or arm lasting for hours or days. There may be a history of local trauma or heavy muscle exertion at the onset of pain. As mentioned, the patient may complain of weakness of the forearm muscles innervated by the anterior interosseous nerve. Theoretically, there should be no sensory complaints [6].

Physical Examination

Pronator Teres Syndrome

Findings may be ill-defined and difficult to substantiate in pronator teres syndrome [5,14]. The most important physical finding is tenderness over the proximal forearm. Pressure over the pronator teres muscle produces discomfort and may produce a radiating pain and digital numbness. The symptomatic pronator teres muscle may be firm to palpation compared with the other side. The contour of the forearm may be depressed, caused by the thickening of the lacertus fibrosus. Distinctive findings are weakness of both the intrinsic muscles of the hand supplied by the median nerve and the muscles proximal to the wrist and in the forearm with

tenderness, Tinel sign over the point of entrapment, and absence of Phalen sign. Pain may be elicited by pronation of the forearm, elbow flexion, or even contraction of the superficial flexor of the second digit. Sensory examination findings are usually poorly defined but may involve not only the median nerve distribution of the digits but also the thenar region of the palm because of involvement of the palmar cutaneous branch of the median nerve. Deep tendon reflexes and cervical examination findings should be normal [7,12,13,15–19].

Anterior Interosseous Syndrome

To test the muscles that the anterior interosseous nerve innervates [5,14], the clinician braces the metacarpophalangeal joint of the index finger and the patient is asked to flex only the distal phalanx. This isolates the action of the flexor digitorum profundus on the terminal phalanx and eliminates the action of the flexor digitorum superficialis. There is no terminal phalanx flexion if the anterior interosseous nerve is injured.

Another useful test is to ask the patient to make the “OK” sign [20]. In anterior interosseous syndrome, the distal interphalangeal joint cannot be flexed, and this results in the index finger’s remaining relatively straight during this test (Fig. 24.3). The patient is asked to forcefully approximate the finger pulps of the first and second digits. The patient with weakness of the flexor pollicis longus and digitorum profundus muscles cannot touch with the pulp of the fingers, but rather the entire volar surfaces of the digits are in contact. This is due to the paralysis of the flexor pollicis longus and flexor digitorum profundus of the second digit. The pronator quadratus is difficult to isolate clinically, but an attempt can be made by flexing the forearm and asking the patient to resist

supination. Sensation and deep tendon reflexes should be normal [7,12,13,15–19].

Functional Limitations

Pronator Teres Syndrome

In pronator teres syndrome, there is clumsiness, loss of dexterity, and a feeling of weakness in the hand. This may lead to functional limitations both at home and at work. Repetitive elbow motions, such as hammering, cleaning fish, serving tennis balls, and rowing, are most likely to provoke symptoms.

Anterior Interosseous Syndrome

As weakness develops in anterior interosseous syndrome, there is loss of dexterity and pinching motion with difficulty in picking up small objects with the first two digits. Activities of daily living, such as buttoning shirts and tying shoelaces, can be impaired. Patients may have difficulty with typing, handwriting, cooking, and so on.

Diagnostic Studies

Pronator Teres Syndrome

Electrodiagnostic testing (nerve conduction studies and electromyography) is the “gold standard” for confirming pronator teres syndrome [4,21,22]. Results of nerve conduction studies may be abnormal in the median nerve distribution; however, the diagnosis may be best established by electromyographic studies demonstrating membrane instability (including increased insertional activity, fibrillation and positive sharp waves at rest, wide and high amplitude polyphasic on minimal contraction, and decreased recruitment pattern on maximal contraction) of the median nerve muscles below and above the wrist in the forearm but

FIGURE 24.3 The anterior interosseous nerve innervates the flexor pollicis longus as well as the flexor digitorum profundus to the index and long fingers. **A**, It is responsible for flexion of the thumb interphalangeal joint and the index finger distal interphalangeal joint. **B**, An injury to the median nerve high in the forearm or to the anterior interosseous branch of the median nerve results in inability to forcefully flex these joints. (From Concannon MJ. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

with *sparing of the pronator teres* [22,23]. Imaging studies (e.g., radiography, computed tomography, hypoechoic swelling by ultrasonography, and magnetic resonance imaging) are used to exclude alternative diagnoses. Magnetic resonance imaging and high-resolution ultrasonography may be helpful in diagnosis, although there is no consensus on which is the preferred method [24–29].

Anterior Interosseous Syndrome

Electrodiagnostic studies may also help establish the diagnosis of anterior interosseous syndrome [5]. In general, the results of routine motor and sensory studies are normal. The most appropriate technique is surface electrode recording from the pronator quadratus muscle with median nerve stimulation at the antecubital fossa. On electromyography, findings of membrane instability are restricted to the flexor pollicis longus, flexor digitorum profundus (of the second and third digits), and pronator quadratus [9,21].

Imaging studies are useful in excluding other diagnoses. [25–29]

Differential Diagnosis

PRONATOR TERES SYNDROME

Carpal tunnel syndrome
Cervical radiculopathy, particularly lesions affecting C6 or C7
Thoracic outlet syndrome with involvement of the medial cord
Elbow arthritis
Epicondylitis

ANTERIOR INTEROSSEOUS SYNDROME

Paralytic brachial plexus neuritis
Entrapment or rupture of the tendon of the flexor pollicis longus
Rupture of the flexor pollicis longus and flexor digitorum profundus

Treatment

Initial

Pronator Teres Syndrome

Treatment is initially conservative, with rest and avoidance of the offending repetitive trauma [6,14]. A wrist immobilization splint is applied in 15 degrees of dorsiflexion for 4 to 6 weeks. The patient is instructed in friction massage. Ice and electrical stimulation are instituted three times a week for 10 treatments. The splint is discontinued at a time determined by the physician [30]. Nonsteroidal anti-inflammatory drugs may help with pain and inflammation. Analgesics may be used for pain. Low-dose tricyclic antidepressants may be used for pain and to help with sleep. Antiseizure medications are also often used for neuropathic pain (e.g., carbamazepine, gabapentin).

Anterior Interosseous Syndrome

Treatment of the anterior interosseous syndrome depends on the cause [5,14]. Penetrating wounds require immediate exploration and repair. Impending Volkmann contracture demands immediate decompression. In spontaneous cases

associated with specific occupations, a trial of nonoperative therapy is indicated. If spontaneous improvement does not occur by 6 to 8 weeks, consideration should be given to surgical exploration. Conservative management includes avoiding the activity that exacerbates the symptoms. Pharmacologic treatment is similar to that for pronator teres syndrome.

Rehabilitation

Pronator Teres Syndrome

A splint that can put the thumb in an abducted, opposed position, such as a C bar or a thumb post–static orthosis, can be used (Fig. 24.4) [8,9,11]. Taping of the index and middle fingers in a buddy splint to stabilize the lack of distal interphalangeal flexion may be helpful [11].

Rehabilitation may include modalities such as ultrasound, electrical stimulation, iontophoresis, and phonophoresis. The patient can be instructed in ice massage as well. Once the acute symptoms have subsided, physical or occupational therapy can focus on exercises to improve forearm flexibility, muscle strength responsible for thumb abduction, opposition, and wrist radial flexion.

Anterior Interosseous Syndrome

Resting the arm by immobilization in a splint may be tried (Fig. 24.5) [31]. If the symptoms subside, conservative physical or occupational therapy, including physical modalities as previously described and exercises to improve strength and function of the pronator quadratus, flexor digitorum profundus, and flexor pollicis longus, can be initiated [11].

Procedures

In both anterior interosseous and pronator teres syndromes, a median nerve block may be attempted [32] (Figs. 24.6 and 24.7).

FIGURE 24.4 A typical splint used in pronator teres syndrome.

FIGURE 24.5 A typical splint used in anterior interosseous syndrome.

Surgery

Pronator Teres Syndrome

If symptoms fail to resolve, surgical release of the pronator teres muscle and any constricting bands (ligament of Struthers and lacertus fibrosus) should be considered with direct exploration of the area. Traditionally, an S-shaped incision is typically used to extensively expose the entire median nerve from the forearm to the hand [33]. Recent techniques have elucidated the possible advantage of using small-incision endoscopic procedures [34,35].

Anterior Interosseous Syndrome

If spontaneous improvement does not occur by 6 to 8 weeks, consideration should be given to surgical exploration. The surgical technique for exploration is exposure of the median nerve directly beneath the pronator teres or separation of this muscle from the flexor carpi radialis, identification of the anterior interosseous nerve, and release of the offending structures.

If surgical decompression was performed and failed to resolve the weakness, tendon transfers may be considered after a more proximal fascicular lesion is ruled out [33]. Endoscopically assisted technique has been tried but without much success at this point because of the depth of the surgical approach and limited view [36].

Postoperative Rehabilitation [30]

0 to 1 week

Postoperative dressing is removed. Active and gentle passive range of motion exercises are initiated for 15 minutes per hour. Desensitization and edema management are instituted. Pronation and elbow extension stretching exercises are instituted four times a day.

3 weeks

Strengthening is initiated in accordance with the patient's comfort level using putty, Hand Helper, and Thera-Band.

Potential Disease Complications

Pronator Teres Syndrome

Disease-related complications, if the condition is left unresolved, include permanent loss of the use of the pinch grasp, lack of wrist flexion, and incessant pain.

Anterior Interosseous Syndrome

If it is allowed to persist, this syndrome will cause inability to perform the pinch grasp, resulting in the functional deficits mentioned before.

Potential Treatment Complications

Use of anti-inflammatory medications such as nonsteroidal anti-inflammatory drugs can induce gastric, renal, and hepatic side effects. Local steroid injections can induce skin depigmentation, local atrophy, or infection. Surgical complications include infection, bleeding, and injury to surrounding structures.

FIGURE 24.6 Pronator teres nerve block. At the elbow crease, make a mark at the midpoint between the medial epicondyle and the biceps tendon. Then, under sterile conditions, insert a 25-gauge, 1½-inch disposable needle into the pronator teres muscle approximately 2 cm below the mark or at the point of maximal tenderness in the muscle. Confirmation of needle placement can be made by a nerve stimulator. Then, inject 3 to 5 mL of a corticosteroid-anesthetic solution (e.g., 2 mL of methylprednisolone [40 mg/mL] combined with 2 mL of 1% lidocaine). Postinjection care may include icing for 10 to 15 minutes and splinting of the wrist and forearm in a functional position for a few days. Also, the patient should be cautioned to avoid aggressive use of the arm for at least 1 to 2 weeks. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

FIGURE 24.7 Anterior interosseous nerve block. The anterior interosseous nerve can be blocked by either an anterior or a posterior approach. For the posterior approach, the posterior elbow is exposed and the forearm is placed in neutral. Under sterile conditions with use of a 2-inch, 25-gauge disposable needle, inject 3 to 5 mL of a corticosteroid-anesthetic solution (e.g., 2 mL of methylprednisolone [40 mg/mL] combined with 2 mL of 1% lidocaine) approximately 5 cm distal to the tip of the olecranon. The needle should penetrate about 3.5 to 5 cm toward the biceps tendon insertion at the radius. A nerve stimulator is necessary to ensure proper placement. Postinjection care is similar to that of the pronator teres nerve block. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

 M70.21 Olecranon bursitis, right elbow
 M70.22 Olecranon bursitis, left elbow

Definition

Olecranon bursitis is a swelling of the subcutaneous, synovium-lined sac that overlies the olecranon process. The bursa functions to cushion the tip of the olecranon and to reduce friction between the olecranon and the overlying skin during elbow motion. Because of the paucity of soft tissue covering the elbow, the olecranon bursa is susceptible to injury.

The causes of olecranon bursitis can be classified as traumatic, inflammatory, septic, and idiopathic [1]. Traumatic bursitis may result from a single, direct blow to the elbow or from repetitive stress. Football players, particularly those who play on artificial turf, are at risk for development of acute bursitis. More commonly, repeated minor trauma from direct pressure on the elbow or elbow motion is responsible for the problem. Trauma is thought to stimulate increased vascularity, resulting in bursal fluid production and fibrin coating of the bursal wall [2]. Persons engaged in certain occupations or certain activities are susceptible to olecranon bursitis, including auto mechanics, gardeners, plumbers, carpet layers, students, gymnasts, wrestlers, and

dart throwers. Interestingly, approximately 7% of hemodialysis patients develop olecranon bursitis [3]. Repeated, prolonged positioning of the elbow and anticoagulation appear to be contributing factors.

Inflammatory causes include diseases that affect the bursa primarily, such as rheumatoid arthritis, gout, and chondrocalcinosis. Olecranon bursitis is commonly seen in rheumatoid patients, in whom the bursa may actually communicate with the affected elbow joint. Crystal-induced olecranon bursitis may be difficult to differentiate from septic bursitis.

Septic olecranon bursitis represents 20% of olecranon bursitis [4]. The source is most often transcutaneous, and about half have identifiable breaks in the skin. When culture samples are positive, the bursal fluid usually contains *Staphylococcus aureus* [5]. Sepsis is unusual. Both underlying bursal disease (gout, rheumatoid arthritis, chondrocalcinosis) and systemic conditions such as diabetes mellitus, uremia, alcoholism, injection drug use, and steroid therapy are considered predisposing factors. There appears to be a seasonal trend, with a peak of staphylococcal septic bursitis during the summer months [6].

In approximately 25% of cases, no identifiable cause of the olecranon bursitis is found. Presumably, repetitive, minor irritation is responsible for the bursal swelling.

Symptoms

Painless swelling is the chief complaint in noninflammatory, aseptic olecranon bursitis. When patients are asymptomatic, they usually have discomfort when the elbow is flexed beyond 90 degrees and have trouble resting on the elbow. Moderate to severe pain is the predominant complaint of patients with septic or crystal-induced olecranon bursitis. These patients may also have fever, malaise, and limited elbow motion.

Physical Examination

The physical examination varies somewhat, depending on the underlying condition. With noninflammatory aseptic bursitis, a nontender fluctuant mass is present over the tip of the elbow (Fig. 25.1). Elbow motion is usually full and painless. With chronic bursitis, the fluctuance may be replaced with a thickened bursa (Fig. 25.2).

The distinction between crystal-induced and septic bursitis may be subtle. Both conditions may produce tender fluctuance, induration, swelling, warmth, and local erythema.

FIGURE 25.1 Athermatous olecranon bursitis in a 55-year-old woman. A large, fluctuant mass is present.

FIGURE 25.2 Chronic gouty olecranon bursitis. The prominence at the tip of the elbow is firm with thinning of the overlying skin.

Elbow flexion may be somewhat limited, although not as limited as with septic arthritis of the elbow joint. Fever and a break in the skin over the elbow are important clues to an underlying septic process (Fig. 25.3). Cellulitis extending distally along the forearm is also more likely to be due to an infection.

In inflammatory cases, pain inhibition may produce mild weakness of elbow flexion and extension. Sensation and distal pulses are unaffected. Examination findings of other joints should also be normal.

Functional Limitations

Functional limitations depend on the underlying diagnosis. Traumatic olecranon bursitis usually causes minimal functional limitation. Patients may note some mild discomfort with direct pressure over the tip of the elbow (e.g., when sitting at a desk or resting the arm on the armrest of a chair or in the car). With crystal-induced and septic bursitis, pain is the predominant issue. Patients may have trouble sleeping and have difficulty with most activities of daily living that involve the affected extremity (e.g., dressing, grooming, cleaning, shopping, and carrying packages).

FIGURE 25.3 Septic olecranon bursitis. Cellulitis is present over a wide area. The white scab at the tip of the elbow represents the site of the penetrating injury. Distally, the draining area of granulation tissue developed at the site of needle aspiration. Aspiration of the bursa should be done by use of a long needle inserted well away from the fluctuant area.

Diagnostic Studies

The diagnosis of aseptic, noninflammatory olecranon bursitis is usually straightforward, based on a characteristic appearance on physical examination. In this setting, additional studies are not usually necessary. However, plain radiographs may demonstrate an olecranon spur in about one third of cases (Fig. 25.4). Because this is an extra-articular process, a joint effusion is not present.

If crystal-induced or septic bursitis is suspected, aspiration of the bursal fluid is usually indicated. The fluid should be sent for cell count, Gram stain and culture, and crystal analysis. Acute, traumatic bursal fluid typically has a serosanguineous appearance, containing fewer than 1000 white blood cells per high-power field, with a predominance of monocytes. Infected bursal fluid usually contains an increased white blood cell count, with a high percentage of polymorphonuclear cells. The Gram stain is positive in only 50% of septic cases. Even in the setting of infection, the fluid should be examined under a polarizing microscope because simultaneous infectious and crystal-induced arthritis can occur [7].

FIGURE 25.4 Lateral radiograph of the elbow in a patient with chronic olecranon bursitis. Note the olecranon spur.

A complete blood cell count and determination of serum uric acid level may provide supportive information in confusing cases, although a normal serum white blood cell count does not preclude septic bursitis.

Magnetic resonance imaging may be of some value to distinguish septic from nonseptic olecranon bursitis, although there is considerable overlap of findings [8]. Absence of bursal and soft tissue enhancement is consistent with nonseptic olecranon bursitis. Olecranon marrow edema is suggestive but not diagnostic of septic olecranon bursitis. The use of magnetic resonance imaging may also help clarify the diagnosis of unusual masses around the elbow.

Differential Diagnosis

- Rheumatoid nodule
- Lipoma
- Tophus
- Elbow synovitis
- Olecranon spur

Treatment

Initial

Treatment of traumatic olecranon bursitis begins with prevention of further injury to the involved elbow. An elastic elbow pad provides compression and protects the bursa. The patient should be counseled in ways of protecting the elbow at work and during recreation. Nonsteroidal anti-inflammatory drugs are usually prescribed. Traumatic, noninflammatory bursitis usually resolves with this treatment [9]. On occasion, when the bursa is very large, aspiration of the bloody fluid will be a first-line treatment. This is followed by application of a compressive wrap and splint for several days.

In suspected cases of septic olecranon bursitis, it is important to palpate for fluctuance. If a fluid collection is appreciated, the bursa should be aspirated (see the section on procedures). When cellulitis over the tip of the elbow is present without an obvious collection, empirical treatment with antibiotic therapy to cover penicillin-resistant *S. aureus*, the most common offender, is recommended. (Less common organisms include group A streptococcus and *Staphylococcus epidermidis*.) The decision whether to use oral or intravenous antibiotics depends on the appearance of the elbow, the signs of systemic illness, and the general health of the patient. The elbow should be splinted in a semiflexed position (approximately 60 degrees) without pressure on the olecranon. Nonsteroidal anti-inflammatory drugs may be prescribed unless they are contraindicated for empirical treatment of gout and pseudogout. When final culture results return, the antibiotic therapy is adjusted appropriately. Outpatient cases are observed closely, with any changes in the size of the bursa and the quality of the overlying skin noted; oral antibiotic therapy should continue for at least 10 days.

Patients with extensive infection or underlying bursal disease, systemic disease, or immunosuppression and outpatients refractory to oral treatment should be treated with an intravenous cephalosporin. In one study, the average duration of intravenous therapy was 4.4 days if symptoms had

been present for less than 1 week and 9.2 days if symptoms had been present for longer than 1 week [10]. The conversion to oral antibiotics should occur only after consistent improvement is seen in the appearance of the patient and the elbow. Serial aspirations may also constitute part of the therapy; alternatively, some clinicians use a suction irrigation system placed into the bursa. Surgical consultation is recommended if the bursitis has failed to improve within several days of appropriate management.

Rehabilitation

Because the process is extra-articular, permanent elbow stiffness is not usually a problem. Physical or occupational therapy for gentle range of motion may be indicated once the olecranon wound has clearly healed. Extreme flexion should be avoided early on because this position puts tension on the already compromised skin. If prolonged immobilization is necessary to permit the soft tissues to heal, therapy may include range of motion and strengthening of the arm and forearm.

Patients who have traumatic or recurrent olecranon bursitis should be counseled in ways to modify their home and work activities to eliminate irritation to the bursa. This might include the use of ergonomic equipment, such as forearm rests (also called data arms) that do not contact the elbow. In some instances, vocational retraining may be indicated.

Procedures

Needle aspiration is therapeutic as well as diagnostic and usually reduces symptoms (Fig. 25.5). It can be performed for patients with traumatic bursitis if they have symptoms compromising their regular activities and should be done (as previously described) for patients in whom inflammatory or septic causes are suspected.

The elbow is prepared in a sterile fashion. The skin is infiltrated locally with 1% lidocaine (Xylocaine). To minimize the risk of persistent drainage after aspiration, it is

FIGURE 25.5 Approach for olecranon aspiration and injection.

recommended to insert a long 18-gauge needle at a point well proximal to the tip of the elbow. The bursa should be drained as completely as possible. The fluid should be sent for Gram stain, culture and sensitivity, cell count, and crystal analysis.

Postinjection care includes local icing for 10 to 20 minutes. A sterile compressive dressing is then applied, followed by an anterior plaster splint that maintains the elbow in 60 degrees of flexion.

Corticosteroid injections into the bursa have been shown to hasten the resolution of traumatic and crystal-induced olecranon bursitis [11]. However, the risk of complications is high, including infection, skin atrophy, and chronic local pain. Consequently, the routine use of steroid injections for olecranon bursitis is not recommended.

Surgery

Surgery is rarely indicated for traumatic olecranon bursitis. Chronic drainage of bursal fluid is the most common indication for surgery [1]. Bursectomy is conventionally done through an open technique, although a recently developed arthroscopic method has shown some promise. Surgery is usually curative for both traumatic and septic bursitis. However, the success rates are very different for patients with rheumatoid arthritis; surgery provides successful relief for 5 years in only 40% of patients with rheumatoid arthritis versus 94% of nonrheumatoid patients [12].

After surgery, suction drains are often placed for several days. Splinting of the elbow at 60 degrees of flexion or greater for 2 weeks is thought to help prevent recurrence.

Potential Disease Complications

Septic bursitis poses the greatest threat with regard to disease complications. If it is neglected, the infection may thin the overlying skin and eventually erode through it (Fig. 25.6). This complication is difficult to manage, often requiring extensive débridement and flap coverage. Persistent infection can also result in osteomyelitis of the olecranon process. Immunocompromised patients are at risk for sepsis from olecranon bursitis. Necrotizing fasciitis originating from a septic olecranon bursitis, although rare, may prove to be fatal.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects on the gastric, hepatic, and renal systems. Persistent drainage from a synovial fistula is an uncommon complication of aspiration of the olecranon bursa; however, this problem is serious enough to discourage the routine aspiration of olecranon bursal fluid

FIGURE 25.6 Untreated septic bursitis with a large olecranon ulcer. The periosteum of the olecranon is visible in the wound. This problem is difficult to manage and often requires flap coverage.

in noninflammatory conditions. Complications of steroid injection, as described earlier, can be serious. In addition, wound problems are the major complication associated with surgical treatment of olecranon bursitis. Because of the superficial location of the olecranon and the tenuous blood supply of the overlying skin, wound healing can be difficult. Malnourished and chronically ill patients are especially at risk for surgical complications.

ICD-10 Codes

G56.30 Lesion of radial nerve, unspecified upper limb
 G56.31 Lesion of radial nerve, right upper limb
 G56.32 Lesion of radial nerve, left upper limb

Definition

The radial nerve originates from the C5 to T1 roots. These nerve fibers travel along the upper, middle, and lower trunks. They continue as the posterior cord and terminate as the radial nerve.

The radial nerve is prone to entrapment in the axilla (crutch palsy), the upper arm (spiral groove), the forearm (posterior interosseous nerve), and the wrist (cheiralgia paresthetica). Radial neuropathies can result from direct nerve trauma, compressive neuropathies, neuritis, or complex humerus fractures [1].

In the proximal arm, the radial nerve gives off three sensory branches (posterior cutaneous nerve of the arm, lower

lateral cutaneous nerve of the arm, and posterior cutaneous nerve of the forearm). The radial nerve supplies a motor branch to the triceps and anconeus before wrapping around the humerus in the spiral groove, a common site of radial nerve injury. The nerve then supplies motor branches to the brachioradialis, the long head of the extensor carpi radialis, and the supinator. Just distal to the lateral epicondyle, the radial nerve divides into the posterior interosseous nerve (a motor nerve) and the superficial sensory nerve (a sensory nerve). The posterior interosseous nerve supplies the supinator muscle and then travels under the arcade of Frohse (another potential site of compression) before coursing distally to supply the extensor digitorum communis, extensor digiti minimi, extensor carpi ulnaris, abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis, and extensor indicis proprius. The superficial sensory nerve supplies sensations to the dorsum of the hand, excluding the fifth and ulnar half of the fourth digit, which is supplied by the ulnar nerve (Fig. 26.1). Radial neuropathy is relatively uncommon compared with other compressive neuropathies of the upper limb. A study in 2000 showed that the annual age-standardized rates per 100,000 of new presentations in primary care were 2.97 in men and 1.42 in women for radial neuropathy, 87.8 in men and 192.8 in women for carpal tunnel syndrome, and 25.2 in men and 18.9 in women for ulnar neuropathy [2].

Symptoms

Symptoms of radial neuropathy depend on the site of nerve entrapment [3] (Table 26.1). In the axilla, the entire radial nerve can be affected. This may be seen in crutch palsy if the patient is improperly using crutches in the axilla, causing compression. With this type of injury, the median, axillary, or suprascapular nerves may also be affected. All radially innervated muscles (including the triceps) as well as sensation in the posterior arm, forearm, and dorsum of the hand may be affected.

The radial nerve is especially prone to injury in the spiral groove (also known as Saturday night palsy or hon-eymooner's palsy). Symptoms include weakness of all radially innervated muscles except the triceps and sensory changes in the posterior arm and hand. In the forearm, the radial nerve is susceptible to injury as it passes through

FIGURE 26.1 Neural branching of the radial nerve. Its origin in the axilla to the termination of its motor and sensory branches is shown. The inset demonstrates the cutaneous distribution of the various sensory branches of the radial nerve. (From Haymaker W, Woodhall B. *Peripheral Nerve Injuries*. Philadelphia, WB Saunders, 1953.)

the supinator muscle and the arcade of Frohse. Because the superficial radial sensory nerve branches before this area of impingement, sensation will be spared. The patient will complain of weakness in the wrist and finger extensors. On occasion, the superficial radial sensory nerve

is entrapped at the wrist, usually as a result of lacerations at the wrist or a wristwatch that is too tight. In this situation, the symptoms will be sensory, involving the dorsum of the hand.

Physical Examination

The findings on physical examination depend on where the injury is along the anatomic course of the nerve. A Tinel sign may be present at the site of compression. Injury in the axilla will lead to weakness in elbow extension, wrist extension, and finger extension. The entire sensory distribution of the radial nerve will be affected. If the injury is in the spiral groove, the examination findings will be the same, except that *triceps function will be spared*. Radial neuropathy in the forearm will usually result in sparing of sensory functions. If the nerve is entrapped in the supinator muscle, supinator strength should be normal. This is because the branch to innervate the supinator muscle is given off proximal to the muscle. The patient will have radial deviation with wrist extension and weakness of finger extensors. Injury to the superficial radial sensory nerve will result in paresthesias or dysesthesias over the radial sensory distribution in the hand.

Functional Limitations

The prognosis for patients with acute compressive radial neuropathies is good [4]. Functional limitation depends on the extent of the injury and the level of the lesion. In high radial nerve palsy, wrist and finger extension are impaired. However, the inability to stabilize the wrist in extension leads to the main functional limitation. The loss of the power of the wrist and finger extensors destroys the essential reciprocal tenodesis action vital to the normal grasp and release pattern of the hand and results in ineffective finger flexion function. Activities such as gripping or holding objects will therefore be impaired. The sensory loss associated with radial nerve palsy is of lesser functional consequence compared with that of median or ulnar nerve lesions. Sensory loss is limited to the dorsoradial aspect of the hand, and this leaves the more functionally important palmar surface intact. Pain from posterior interosseous nerve entrapment can be disabling enough to limit the function of the involved extremity.

Diagnostic Studies

Electrodiagnostic testing (electromyography and nerve conduction studies) is the most useful test to assess for radial neuropathies. This test can be used to diagnose, to localize, to prognosticate, and to rule out other nerve injuries. The test is usually performed 3 weeks after the onset of clinical findings [5]. At this time, muscle denervation potentials will be observed if axonal injury is present. Radiography and magnetic resonance imaging can be used to rule out a mass (ganglion or tumor) [6] or fracture [7,8] as the reason for the radial neuropathy. Studies have used ultrasound (Fig. 26.2) to investigate the appearance of the radial nerve in the lateral aspect of the distal upper arm [9–11].

Table 26.1 Extensor Tendon Compartments—Wrist

Muscles	Insertion	Evaluation
Abductor pollicis longus	Dorsal base of thumb metacarpal	Bring thumb out to side
Extensor pollicis brevis	Proximal phalanx of the thumb	
Extensor carpi radialis longus	Dorsal base of index and middle metacarpals	Dorsiflex the wrist with the hand in a fist and apply resistance radially
Extensor carpi radialis brevis		Hand flat on table
Extensor pollicis longus	Distal phalanx of the thumb	Lift only thumb
Extensor digitorum communis	Extensor hood and base of proximal phalanges of the ulnar four digits	Extend fingers with wrist in neutral
Extensor indicis proprius		Extend index finger
Extensor digiti minimi	Proximal phalanx of the little finger	Straighten little finger with other fingers in fist
Extensor carpi ulnaris	Dorsal base of the fifth metacarpal	Wrist extension with ulnar deviation

FIGURE 26.2 Short-axis ultrasound image of the radial nerve at the elbow between the heads of the supinator muscle.

Differential Diagnosis

Cervical radiculopathy (C6, C7)
 Brachial neuritis
 Posterior cord brachial plexopathy
 Upper or middle trunk brachial plexopathy
 Extensor tendon rupture
 Epicondylitis
 de Quervain tenosynovitis
 Wristdrop secondary to lead polyneuropathy
 Posterior interosseous nerve mononeuropathy
 Peripheral neuropathy
 Axillary nerve injury
 Tumor
 Chondroma [13]
 Hematoma
 Carpal tunnel syndrome
 Upper extremity extensor compartment syndrome
 Ulnar neuropathy
 Entrapment neuropathy due to chronic injection-induced triceps fibrosis [14]
 Superficial radial neuropathy caused by intravenous injection [15]
 Neuropathy after vascular access cannulation for hemodialysis [12]

Treatment

Initial

Radial neuropathies from compression can be managed conservatively in nearly all cases. Elimination of offending factors, such as improper use of crutches, and avoidance of provocative activities are the first steps in the treatment of radial neuropathy. Medications, including tricyclic agents, anticonvulsants, antiarrhythmics, topical solutions, clonidine, and opioids, can be considered for pain management. Nonpharmaceutical treatments, including transcutaneous electrical nerve stimulation and acupuncture, may be considered as adjuvants to medication [12].

Rehabilitation

The main goal of rehabilitation is prevention of joint contractures, shortening of the flexor tendons, and overstretching of the extensors while waiting for nerve recovery. This can be achieved by exercises to maintain range of motion, passive stretching, and proper splinting. Functional splinting can make relatively normal use of the hand possible. Dynamic splints use elastic to passively extend the finger at the metacarpophalangeal joints with the wrist immobilized in slight dorsiflexion. This provides stability to the wrist joint, passive extension of the digits by the elastic band, and active flexion of the fingers. A splint designed at the Hand Rehabilitation Center in Chapel Hill, North Carolina, uses a static nylon cord rather than a dynamic rubber band to suspend the proximal phalanges (Fig. 26.3). The design simulates the tenodesis action of the normal grasp and release pattern of the hand.

Postsurgical release of compression should be immediately followed by exercises to increase or to maintain range of motion and a nerve gliding program to prevent adhesions. Overly aggressive strengthening should be avoided during reinnervation. In tendon transfers, preoperative strengthening of the muscle to be transferred and postoperative muscle reeducation are vital to the success of the procedure.

Procedures

Local anesthetic blocks or injections of hydrocortisone can be used [16] but are rarely necessary and have shown

FIGURE 26.3 Radial palsy splint with metacarpophalangeal joint extended and flexed.

only temporary symptomatic relief. Lateral epicondylitis may mimic posterior interosseous nerve entrapment at the elbow. When lateral epicondylitis does not respond to conservative treatment, including injections of the lateral epicondyle, a diagnostic and therapeutic radial nerve injection at the elbow may be indicated [17].

Surgery

Surgical decompression may be required for patients who do not respond to conservative treatment or patients with severe nerve injury. Radial tunnel release has been advocated for compression neuropathies of the posterior interosseous nerve, but the results have been questionable [18]. Surgical intervention for anastomosis may be indicated in cases of complete radial injury (neurotmesis). Tendon transfers may be considered in these instances if the surgery is not performed or is not successful [19,20]. Care must be exercised to avoid the radial sensory branch during operations involving the wrist [16]. Surgery has been noted to be less successful if there are coexisting additional nerve compressions or lateral epicondylitis or if the patient is receiving workers' compensation [21].

Potential Disease Complications

Patients with incomplete recovery may suffer significant functional loss in the upper extremity. Like any patient with nerve injury, they are at risk for development of complex

regional pain syndrome (reflex sympathetic dystrophy) [22]. Contractures and chronic pain may develop as well.

Potential Treatment Complications

There are inherent risks with any surgery, including failure to correct the problem, infection, additional deformity, and death. Any injection or surgery involving the wrist should avoid the superficial radial sensory nerve as this could cause additional paresthesias or dysesthesias.

Ulnar neuritis
Compression of the ulnar nerve

ICD-9 Code

354.2 Lesion of ulnar nerve

ICD-10 Codes

G56.20 Lesion of ulnar nerve, unspecified upper limb
G56.21 Lesion of ulnar nerve, right upper limb
G56.22 Lesion of ulnar nerve, left upper limb

Definition

The ulnar nerve is derived predominantly from the nerve roots of C8 and T1 with a small contribution from C7. The C8 and T1 fibers form the lower trunk of the brachial plexus. The ulnar nerve is the continuation of the medial cord of the brachial plexus at the level of the axilla.

Ulnar neuropathy at the elbow is the second most common entrapment neuropathy. Only carpal tunnel syndrome (median neuropathy at the wrist) is more frequent. The ulnar nerve is susceptible to compression at the elbow for several reasons. First, the nerve has a superficial anatomic location at the elbow. Hitting the “funny bone” (ulnar nerve at the elbow) creates an unpleasant sensation that most people have experienced. If the ulnar nerve is susceptible to subluxation, further injury may result. Second, the nerve is prone to repeated trauma from leaning on the elbow or repetitively flexing and extending the elbow. Poorly healing fractures at the elbow may damage

this nerve. Finally, and perhaps most important, the ulnar nerve can become entrapped at the arcade of Struthers, in the cubital tunnel (ulnar collateral ligament and aponeurosis between the two heads of the flexor carpi ulnaris; Fig. 27.1), or within the flexor carpi ulnaris muscle. The nerve lengthens and becomes taut with elbow flexion. In addition, there is decreased space in the cubital tunnel in this position. The volume of the cubital tunnel is maximal in extension and can decrease by 50% with elbow flexion [1]. The nerve may also become compromised after a distal humerus fracture, either as a direct result of the fracture or because of an altered carrying angle of the elbow and decreased elbow extension (tardy ulnar palsy). Repetitive or incorrect throwing can lead to damage of the ulnar nerve at the elbow [2]. Biomechanical risk factors (repetitive holding of a tool in one position), obesity, and other associated upper extremity work-related musculoskeletal disorders (especially medial epicondylitis and other nerve entrapment disorders) have also been associated with the development of ulnar neuropathy at the elbow [3].

Symptoms

If the ulnar nerve is entrapped at the elbow, both the dorsal ulnar cutaneous nerve (which arises just proximal to the wrist) and the palmar cutaneous branch of the ulnar nerve will be affected. Patients will therefore complain of numbness or paresthesias in the dorsal and volar aspects of the fifth and ulnar side of the fourth digits. Hand intrinsic muscle weakness may be apparent. In cases of severe ulnar neuropathy, clawing of the fourth and fifth digits (with attempted hand opening) and atrophy of the intrinsic muscles may be noted by the patient (Fig. 27.2). Symptoms may be exacerbated by elbow flexion. Pain may be noted and may radiate proximally or distally.

Physical Examination

The ulnar nerve may be palpable in the posterior condylar groove (posterior to the medial epicondyle) with elbow flexion and extension. A Tinel sign may be present at the elbow; however, it should be considered significant only if the Tinel sign is absent on the nonaffected side. The ulnar nerve may be felt subluxing with flexion and extension of the elbow. Sensory deficits may be noted in the fifth and ulnar half of the

FIGURE 27.1 The cubital tunnel. (From Bernstein J, ed. *Musculoskeletal Medicine*. Rosemont, Ill, American Academy of Orthopaedic Surgeons, 2003.)

FIGURE 27.2 Froment sign. Note prominent atrophy of the intrinsic muscles. (From Weiss L, Silver J, Weiss J, eds. *Easy EMG*. New York, Butterworth-Heinemann, 2004.)

fourth digits. Atrophy of the intrinsic hand muscles and hand weakness may be noted as well (although this is generally seen in more advanced cases). Wartenberg sign (abduction of the fourth and fifth digits) may occur. The patient should be tested for Froment sign. Here, a patient is asked to grasp a piece of paper between the thumb and radial side of the second digit. The examiner tries to pull the paper out of the patient's hand. If the patient has injury to the adductor pollicis muscle (ulnar innervated), the patient will try to compensate by using the median-innervated flexor pollicis longus muscle (Fig. 27.2).

Functional Limitations

The patient with ulnar neuropathy at the elbow may have poor hand function and complain of dropping things or clumsiness. There may be difficulty with activities of daily living, such as dressing, holding a pen, or using keys.

Diagnostic Studies

Electrodiagnostic studies can help identify, localize, and gauge the severity of an ulnar nerve lesion at the elbow. The findings of abnormal spontaneous potentials (fibrillations and positive sharp waves) in ulnar innervated muscles on

needle electromyographic study indicate axonal damage and portend a worse prognosis than with injury to the myelin only. Slowing of the ulnar nerve across the elbow or conduction block (a drop in compound motor action potential amplitude across the elbow) indicates myelin injury. These studies can also identify other areas of nerve compression that may accompany ulnar neuropathy at the elbow. Several studies using ultrasound have shown an increased cross-sectional area of the ulnar nerve in patients with ulnar neuropathy at the elbow [4,5]. Magnetic resonance neurography may play a role in the evaluation of ulnar neuropathy at the elbow [6]. Radiographs of the elbow with cubital tunnel views can be obtained if fractures, spurs, arthritis, and trauma are suspected. In rare cases, magnetic resonance imaging [7] with arthrography may be used to assess for tears in the ulnar collateral ligament or soft tissue disease.

Differential Diagnosis

- Ulnar neuropathy at a location other than the elbow
- C8-T1 radiculopathy
- Brachial plexopathy (usually lower trunk)
- Thoracic outlet syndrome
- Elbow fracture
- Elbow dislocation
- Medial epicondylitis
- Carpal tunnel syndrome
- Ulnar collateral ligament injury
- Soft tissue disorders at the elbow

Treatment

Initial

Treatment initially involves relative rest and protecting the elbow. Elbow pads or night splinting in mild flexion may be beneficial. Treatment should be directed at avoidance of aggravating biomechanical factors, such as leaning on the elbows, prolonged or repetitive elbow flexion, and repetitive valgus stress in throwing. Nonsteroidal anti-inflammatory drugs may also be prescribed.

Rehabilitation

Successful rehabilitation of ulnar neuropathy at the elbow includes identification and correction of biomechanical factors. This may include workstation modifications to decrease the amount of elbow flexion, substitution of headphones for telephone handsets, and use of forearm rests. Often, an elbow pad can be beneficial; the pad protects the ulnar nerve and keeps the elbow in relative extension. A rehabilitation program should include strengthening of forearm pronator and flexor muscles. Flexibility exercises should be instituted to maintain range of motion and to prevent soft tissue tightness. Advanced strengthening, including eccentric and dynamic joint stabilization exercises, can be added [8,9].

Procedures

Procedures are not typically performed to treat ulnar neuropathy at the elbow.

Surgery

If conservative management has failed or if significant damage to the ulnar nerve is evident, surgery may be considered [10–12]. The type of surgery depends on the area of ulnar nerve injury and may involve release of the cubital tunnel, ulnar nerve transposition [13], decompression of the ulnar nerve (open or arthroscopic) [14,15], subtotal medial epicondylectomy [16,17], or ulnar collateral ligament repair. Simple decompression and decompression with transposition have been shown to be equally effective in idiopathic ulnar neuropathy at the elbow [18].

Potential Disease Complications

If ulnar neuropathy at the elbow is left untreated, complications may include hand weakness, poor coordination, intrinsic muscle atrophy, sensory loss, and pain. In addition, flexion contractures and valgus deformity may develop at the elbow [8].

Potential Treatment Complications

The results of surgery depend on the extent of ulnar nerve compression, accuracy of identifying the site of compression, type of procedure, thoroughness of compression release, comorbid factors, degree of prior intrinsic muscle loss, and previous sensory loss [8,19–23]. Nonsteroidal anti-inflammatory drugs may cause gastric, hepatic, or renal complications.

M67.20 Other disorders of tendon and
synovium, unspecified site

Definition

Tenosynovitis is inflammation of a tendon and its enveloping synovial sheath [7]. de Quervain tenosynovitis is classically defined as a stenosing tenosynovitis of the synovial sheath of tendons of the abductor pollicis longus and extensor pollicis brevis muscles in the first compartment of the wrist due to repetitive use [2]. Fritz de Quervain first described this condition in 1895 [3]. Histologic studies have found that this disorder is characterized by degeneration and thickening of the tendon sheath and that it is not an active inflammatory condition [8].

In fact, de Quervain described thickening of the tendon sheath compartment at the distal radial end of the extensor pollicis brevis and abductor longus [3]. Extensor triggering, which is manifested by locking in extension, is rare but has also been reported in de Quervain tenosynovitis with a prevalence of 1.3% [1].

Overexertion related to household chores and recreational activities including piano playing, sewing, knitting, typing, bowling, golfing, and fly-fishing have been reported to cause de Quervain tenosynovitis. Workers involved with fast repetitive manipulations such as pinching, grasping, pulling, and pushing are also at risk [6]. Excessive use of the text messaging feature on a cellular phone has now also been linked to this painful condition [9].

For a majority of cases, the onset of de Quervain tenosynovitis is gradual and not associated with a history of acute trauma, although several authors have noted a traumatic etiology, such as falling on the tip of the thumb [6].

de Quervain tenosynovitis primarily affects women (gender ratio approximately 10:1) between the ages of 35 and 55 years. There is no predilection for right versus left side, and no racial differences have been observed [6].

Symptoms

Patients may complain of pain in the lateral wrist during grasp and thumb extension [3]. They may also describe pain

with palpation over the lateral wrist [10]. Symptoms are often gradual in onset and persistent for several weeks or months, and there is often a history of chronic overuse of the wrist and the hand [11]. Pain is the most prominent symptom quality, but some patients report stiffness as well. Pain is often described as severe and may be sufficiently intense to render the hand useless [6]. Paresthesia in the distribution of the anterior terminal branch superficial radial nerve is uncommon [6].

Physical Examination

On examination, the findings of local tenderness and moderate swelling around the radial styloid are likely to be present [11]. A positive Finkelstein test result can confirm the diagnosis [12]. The Finkelstein test is performed by grasping the patient's thumb and quickly abducting the hand in ulnar deviation [4] (Fig. 28.1). Reproduction of pain is a positive test result. A similar test, described by Eichhoff in 1927, provides ulnar deviation while the patient is flexing the thumb and curling fingers around it. Pain should disappear the moment the thumb is again extended, even if the ulnar abduction is maintained [3]. The Eichhoff test is sometimes erroneously called the Finkelstein test. The Brunelli test maintains the wrist in radial deviation while forcibly abducting the thumb [3] (Fig. 28.2). Pain over the radial styloid from these provocative stretch maneuvers differentiates de Quervain tenosynovitis from arthritis of the first metacarpal joint [10]. Strength and sensation are expected to be normal in patients with de Quervain tenosynovitis. However, strength, particularly grip and pinch strength, may be decreased from

FIGURE 28.2 Brunelli test.

pain or disuse secondary to pain [13]. A comprehensive examination of the neck and entire upper extremity should be performed before the wrist examination to rule out radiating pain from a more proximal problem, such as a herniated cervical disc [10]. Assessment of the first carpometacarpal joint, including range of motion, palpation for tenderness and crepitus, and radiographic investigation, should also be performed because injury to this joint can give a false-positive Finkelstein test result [14].

Functional Limitations

Functional impairment is believed to be caused by impaired gliding of the abductor pollicis longus or extensor pollicis brevis tendon through a narrowed fibro-osseous canal [6]. Functional impairment of the thumb is a result of mechanical impingement or pain. Activities of daily living, such as dressing, can be impaired. Fastening of buttons often causes significant pain. In addition, household chores can be limited secondary to pain. Limits in recreational activities, such as bowling, fly-fishing, sewing, and knitting, are also seen in de Quervain tenosynovitis. Workers with jobs requiring repetitive motions, such as pushing or pulling in a factory setting, are at risk for development of the condition. Thus pain from the condition can have a significant economic impact [6].

Diagnostic Studies

Tenosynovitis of the wrist is a clinical diagnosis, but some authors recommend obtaining a wrist radiograph to rule out other potential causes of wrist pain [6]. Some clinicians report that relief of symptoms after injection of a local anesthetic into the first dorsal compartment is often helpful as a diagnostic tool [6]. When clinical findings are nondiagnostic, a bone scan can help confirm the diagnosis [2]. On ultrasound examination, tenosynovitis is characterized by hypoechoic fluid distending the tendon sheath with inflammatory changes within the tendon [15]. Newer studies use ultrasound to evaluate for subcompartmentalization within the first extensor compartment, which may complicate treatment.

FIGURE 28.1 Finkelstein test (A) and Eichhoff test (B).

Differential Diagnosis

Carpal joint arthritis
 Triscaphoid arthritis
 Rheumatoid arthritis
 Intersection syndrome
 Radial nerve injury
 Ganglion cyst
 Cervical radiculopathy
 Scaphoid fracture
 Carpal tunnel syndrome
 Radioscaphoid arthritis
 Kienböck disease
 Extensor pollicis longus tenosynovitis

Treatment

Initial

Initial treatment of de Quervain tenosynovitis is injections. There is no evidence that conservative treatment is effective in reducing symptoms of de Quervain tenosynovitis. Some literature has evaluated effectiveness of ice, nonsteroidal anti-inflammatory drugs (NSAIDs), heat, orthoses, strapping, rest, and massage. Available research does not show these techniques to be effective in the treatment of de Quervain tenosynovitis [6]; however, no randomized controlled study has been performed. One study compared splinting with rest and NSAID therapy. Only 14% of patients who were splinted were cured versus 0% with rest and NSAIDs [16].

Rehabilitation

The goals of therapy are to reduce pain and to improve function of the affected hand. Classically, therapy includes physical modalities such as ice, heat, transcutaneous electrical nerve stimulation, ultrasound, and iontophoresis [8]. In addition, friction massage and active exercises have been employed [8]. A thumb spica splint has been used for immobilization as well [17]. A thumb spica splint is thought to be an effective way to manage symptoms because it inhibits gliding of the tendon through the abnormal fibro-osseous canal [6]. One small, randomized study demonstrated that patients with mild symptoms are more likely to improve with therapy and NSAIDs alone, with the majority of patients with moderate to severe symptoms not responding to therapy [17]. Although steroid injection is the treatment of choice for de Quervain tenosynovitis, because of the benign profile of physical therapy, it is reasonable to consider these less invasive approaches (such as ice, thumb spica splinting, and NSAIDs) as adjuvants when this disorder is mild and first treated [18].

Procedure

Injection of local anesthetics and corticosteroids, with or without immobilization, became popular in the 1950s [6]. It is currently the most frequent treatment modality for patients with de Quervain tenosynovitis. Injection into the first extensor compartment can relieve symptoms (Fig. 28.3). One study described an 83% cure rate with injection [16].

FIGURE 28.3 The four-point injection technique. The injection is divided into two pairs, with each pair including a proximal and distal injection point corresponding with paths of the extensor pollicis brevis and abductor pollicis longus tendons.

In recent years, multiple types of injection techniques have been compared. One study comparing a one-point injection (directed into the first compartment) versus a two-point injection technique (injection corresponding with the paths of both the extensor pollicis brevis and the abductor pollicis longus) showed the latter to be more beneficial [19]. A study evaluating treatment with a four-point injection technique (injecting both the proximal and distal locations for both extensor pollicis brevis and abductor pollicis longus) showed some benefit over the two-point procedure [14]. It is essential that corticosteroid enter the compartment of both the extensor pollicis brevis and abductor pollicis longus for the injection to be effective. Many patients have anatomic variations with a septum creating two subcompartments. Incidence of septation of the first compartment reportedly varies in cadaveric studies from 24% to 76% [20,21]. Ultrasound-guided injections have reportedly increased improvement after injection to 97% [20]. Given the success of injections over therapy, injections remain the first-line treatment of the condition [18].

Surgery

Before 1950, surgery was considered the treatment of choice for de Quervain tenosynovitis. Now, with the success of injections, it is reserved for those whose injection therapy fails [22]. Surgery involves release of the extensor retinaculum, and both open and endoscopic techniques can be used. Partial resection of the retinaculum can be used as well [23]. The patient returns to normal activities after 2 to 3 weeks. On average, surgical success rates range from 83% to 92% [6].

Potential Disease Complications

Because of friction, the tendon sheath becomes edematous, which can further increase friction. This can eventually lead to fibrosis of the tendon [6]. The condition is characterized not by inflammation [6] but by thickening of the tendon sheath and most notably by the accumulation of mucopolysaccharide, an indicator of myxoid degeneration. These changes are pathognomonic of the condition and are

not seen in control tendon sheaths. The term *stenosing tendovaginitis* is a misnomer; de Quervain disease is the result of intrinsic, degenerative mechanisms rather than of extrinsic, inflammatory ones [24].

Potential Treatment Complications

NSAIDs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. The most common immediate adverse reaction reported with injection was pain at the injection site (35%), followed by immediate inflammatory flare reaction (10%), temporary radial nerve paresthesia (4%), and vasovagal reaction (4%); 31% had late adverse reactions ranging from minimal skin color lightening to subcutaneous fat atrophy [6]. In this study, no postinjection infection, bleeding, or tendon rupture was seen, although this could be possible with any injection. With any type of steroid injection, there is a risk of bleeding. Repeated steroid injections have the potential to weaken the tendon and may cause a tendon rupture. Surgical treatment complications include radial nerve injury, incomplete retinacular release, and tendon subluxation [22].

CHAPTER 29

Dupuytren Contracture

Michael F. Stretanski, DO

Synonyms

Dupuytren disease
Viking disease
Cooper contracture

ICD-9 Code

728.6 Dupuytren contracture

ICD-10 Code

M72.0 Dupuytren contracture (palmar fascial fibromatosis)

Definition

Dupuytren disease is a nonmalignant fibroproliferative disorder causing progressive and permanent contracture of the palmar fascia; subsequent flexion contracture usually begins with the fourth and fifth digits on the ulnar side of the hand (Fig. 29.1). The eponym Cooper contracture has been suggested for Astley Cooper, who first described and lectured on the entity in 1822. A nodule in the palm is the primary lesion in Dupuytren contracture. It is a firm, soft tissue mass fixed to both the skin and the deeper fascia. It is characterized histologically by dense, noninflammatory, chaotic cellular tissue and appears on the anterior aspect of the palmar aponeurosis.

The key cell response for tissue contraction in Dupuytren disease is thought to be the fibroblast and its differentiation into a myofibroblast [1]. This idiopathic activation happens in response to the fibrogenic cytokines interleukin-1, prostaglandin F₂, prostaglandin E₂, platelet-derived growth factor, connective tissue–derived growth factor, and, most important, transforming growth factor- β and fibroblast growth factor 2. In addition, microRNAs (miRNAs) identified in Dupuytren contracture samples, including miR-29c, miR-130b, miR-101, miR-30b, and miR-140-3p, were found to regulate important genes related to the β -catenin pathway: *WNT5A*, *ZIC1*, and *TGFB1* [2]. As the nodule extends

slowly, it induces shortening and tension on the longitudinal fascial bands of the palmar aponeurosis, resulting in cords of hypertrophied tissue. It is unique among ailments of the hand, and one could conceive of it as a focal autoimmune collagen vascular phenomenon. Dupuytren disease is thought to begin in the overlying dermis. Unlike the nodule, the cord is strikingly different histologically; it contains few or no myofibroblasts and few fibroblasts in a dense collagen matrix with less vascularity. Skin changes are the earliest signs of Dupuytren disease, including thickening of the palmar skin and underlying subcutaneous tissue. Rippling of the skin can occur before the development of a digital flexion deformity [3].

A controversy exists as to whether there is a relationship between Dupuytren disease and repetitive microtrauma [4], but more recent meta-analysis does seem to suggest some degree of occupational correlation with manual work and vibration exposure [5]. It is now thought that microruptures of the palmar fascia are related to the contracture rather than a primary cause [6]. Cessation of manual labor and immobilization can lead to acceleration of the disease, which has been noted in laborers after retirement [7]. One study seems to suggest that there may be an association with rock climbing in men [8].

A genetic predisposition is thought to be inherited as an autosomal dominant trait with variable penetrance [9]. Family history is often unreliable as many individuals are unaware they have family members with the disease. Dupuytren disease has been termed Viking disease [10] because it has a high prevalence in areas that were populated by the Vikings and where the Vikings migrated. Global prevalence is 3% to 6% of the white population, and it is rare in nonwhite populations. Dupuytren disease occurs more commonly in the elderly but tends to be associated with greater functional compromise in younger patients. Women are affected half as often as men [11]. There is no relationship to handedness; however, affected individuals tend to complain more frequently about the dominant hand. Other associations with the condition include diabetes mellitus [12] (specifically with an increased risk from diet-controlled diabetes to sulfonylureas to metformin to insulin requiring), alcohol consumption [13], cigarette smoking [13,14], human immunodeficiency virus infection [15], and antecedent Colles fracture. Conflicting reports exist of an association with epilepsy, but antiepileptic drugs do not present an increased risk [12,16].

FIGURE 29.1 Typical appearance of ulnar palmar surface after surgical release; notice scarring and incomplete extension.

There are potential secondary findings in Dupuytren disease that are rarely seen but when present suggest a strong Dupuytren diathesis (genetic penetrance of the disease). These findings include knuckle pads (Garrod nodes), plantar fascial disease, and Peyronie disease. The contractile tissue in all of these conditions resembles the pathologic findings of Dupuytren disease in the palm [17], and alterations in the expression of certain gene families, fibroblast to myofibroblast differentiation among others, are similar [18]. However, these associated conditions are found in only an estimated 1% or less of patients with Dupuytren disease [19]. All patients with the disease have a diathesis. The association with these conditions as well as onset at an early age and family history suggests that the diathesis is strong. Recognition of a strong diathesis is important for planning an appropriate rehabilitation protocol, including long-term follow-up and awareness of possible poor prognosis and likelihood of recurrence with surgical treatment.

Symptoms

Dupuytren disease typically has a painless onset and progression. Decreased range of motion, loss of dexterity, and getting the hand “caught” when trying to place it in one’s pant-pocket are common presenting symptoms. Pain can be a result of concomitant injuries to the hand and fingers that can precede the development or worsening of Dupuytren disease. Abrasions or ecchymosis to the distal interphalangeal and proximal interphalangeal joints of the affected digits may be seen and may be the reason for the initial consultation. With use of the relatively new Dupuytren disease scale of subjective well-being of patients questionnaire, which covers four areas of the quality of life, there were no differences in quality of life in patients affected in the left or right hand regardless of hand dominance of the patients [20].

The progression of the condition is generally considered to be a result of immobility after an injury in a predisposed individual rather than of the injury itself. Pure sensory symptoms in digits four and five may arise from palmar digital nerves against the relatively inelastic deep transverse metacarpal ligament.

Physical Examination

The most common first sign of Dupuytren disease is a lump in the palm close to the distal palmar crease and in the axis of the ray of the fourth digit (ring finger) (Fig. 29.2). It can also be manifested in the digit, generally over the proximal phalanx. The thumb and index finger are the least affected of the five digits. The nodule can be tender to palpation. In most cases, the skin is closely adherent to the nodule, and movement with tendon excursion often suggests other conditions, such as stenosing tenosynovitis. The condition is more readily apparent when it is manifested in a more advanced stage with palmar nodule, cord, and digital flexion contracture. Conditions associated with this disease include fat pads at the knuckles and evidence of the disease in the plantar fascia. “Swan-neck” deformity as a dorsal variant of Dupuytren disease has been suggested [21].

The examination should evaluate the range of motion and kinetic chain of the entire upper limb, including associated adhesive capsulitis, epicondylitis, and other tenosynovitis. Sensory, manual motor, and muscle stretch reflex components of the neurologic examination should be normal.

Functional Limitations

The majority of individuals with this condition have little functional limitation early on. With more advanced contracture, properly opening the palm and grasping can become difficult, making gripping activities such as activities of daily living, opening cans, buttoning shirts, and placing keys in automotive ignitions troublesome. In many cases, the insidious onset allows gradual compensation, and outside observers may notice irregularity during a simple hand shake.

Diagnostic Studies

The diagnosis of Dupuytren disease is generally made on a clinical basis. Biopsy is considered when a palmar soft tissue mass cannot be reliably differentiated from sarcoma [22]. The suspicion for sarcoma is higher in a younger individual with no strong evidence of Dupuytren disease because sarcoma is more likely in younger age groups. Unfortunately,

FIGURE 29.2 Dupuytren contracture of the ring finger.

histologic differentiation is not always easy because a Dupuytren nodule can appear cellular with mitotic figures and closely resemble an aggressive sarcoma. Blood work relevant to underlying secondary disease (e.g., hemoglobin A_{1c} level, human immunodeficiency virus testing, uric acid level, erythrocyte sedimentation rate) should be entertained. Electrodiagnostic studies are usually normal. However, concomitant median neuropathy at the wrist or spinal cord may cause sensory loss due to impingement of digital nerves, or Dupuytren tissue may compress the palmar digital nerves against the relatively inelastic deep transverse metacarpal ligament [23]. Sensory nerve action potentials should be recorded to digit four and not just digit five.

Differential Diagnosis

- Fibroma
- Lipoma
- Epithelioid sarcoma
- Giant cell tumor
- Neurofibroma
- Tendon nodules of stenosing tenosynovitis
- Inclusion cysts
- Dorsal Dupuytren disease
- Retinacular ganglions at the A1 pulley
- Non-Dupuytren palmar fascial disease
- Tophi

Treatment

Initial

Many patients who seek consultation for Dupuytren disease are merely looking for reassurance that they do not have a malignant neoplasm and are satisfied to learn that the contracture is not a sign of a more ominous disease.

Conventional noninvasive treatment has generally been of little or no value in the prevention of contracture or recurrence in Dupuytren disease. This includes the use of steroid injections, splinting, ultrasound, and nonsteroidal anti-inflammatory medications. Radiotherapy, topical dimethyl sulfoxide, colchicine, and interferon have also been proposed but lack data demonstrating long-term efficacy. Topical 5-fluorouracil [24], topical imiquimod (Aldara) [25], and oral simvastatin [26] seem to target the underlying fibroblastic process, but long-term outcome studies do not exist. Traumatic rupture has never gained acceptance as a method of correcting flexion contracture; however, anecdotal reports of individuals correcting their deformity in such a fashion exist [27], but recurrence in true Dupuytren disease would be expected. Continuous passive traction has been proposed by some for severely flexed digit contractures [28]; however, this is used as a preoperative adjunctive procedure and not done in isolation.

Ergonomic assessment and equipment modification can be of use in some instances with laborers who are functionally limited by contracture. Tobacco abuse or excessive alcohol consumption should be addressed if applicable.

Rehabilitation

Rehabilitation efforts are minimal preoperatively and focus on adaptive equipment recommendations for work and home (e.g., large-handled tools for gripping). Splinting may be done by therapists with prefabricated or custom designs, but there is no evidence that this delays contracture or affects the underlying pathohistologic changes. Continuous passive traction has been proposed by some for severely flexed digit contractures [26]; however, this is used as a preoperative adjunctive procedure and not done in isolation.

Postoperative rehabilitation is needed to facilitate a satisfactory outcome. The length of the rehabilitation generally reflects the invasiveness of the surgical procedure; limited fasciotomies often involve a period of 4 to 6 weeks, whereas more extensive surgery may necessitate a formal rehabilitation process of up to 3 to 6 months. Stretching, splinting in palmar extension, and continuous passive traction in some individuals are used early postoperatively. Strengthening and functional activities are added later, after incision healing. Again, splinting may be an option to prevent recurrence, and adaptive equipment recommendations can help with resumption of functions that involve gripping or repetitive hand use.

Procedures

Closed needle fasciotomy has been used [29] but is prone to complications, including infection, nerve injury, and skin breakdown as well as recurrence.

Enzymatic fasciotomy with purified collagenase including injection into the central cord has greatly improved nonsurgical relief of contracture [30–32], with recurrence rates in the range of 14% for metacarpophalangeal joints to 23% for proximal interphalangeal joints at 2-year follow-up where initial collagenase treatment was successful [33]. Xiaflex consists of a 1:1 ratio of collagenases, collagenase AUX-I and AUX-II, isolated from the fermentation of *Clostridium histolyticum* bacteria. This agent has been used for débridement of burns and skin ulcers as well as for Peyronie disease [34]. Steroid injection into the palmar nodule can be a useful adjunct to flatten the nodule. Concern for potential adverse effect on the underlying flexor tendons should be noted. Thus, care must be taken to avoid injection into the underlying flexor tendons. Identification of unique miRNA expression in Dupuytren contracture may eventually lead to the development of novel molecular therapy.

Surgery

Appropriate selection is critical for patients considering surgical treatment. The potential for recurrence and worsening after surgery is higher in patients with a strong diathesis. Recurrence is defined as the development of nodules and contracture in the area of previous surgery. Extension is the development of lesions outside of the surgical area where there had previously been no disease. All patients should be made aware that surgery is not curative of this disease and that recurrence and extension are likely at some time. Extensive recurrence is more likely if surgery is performed during the proliferative phase of the condition.

Nevertheless, many individuals have improved hand function after surgical treatment, compared with their preoperative status, for years on follow-up [35]. The goals of surgical treatment, when it is indicated, are to improve function, to reduce deformity, and to prevent recurrence. Surgical indication is generally thought to include digital flexion contracture of the proximal interphalangeal and metacarpophalangeal joints and web space contracture. Metacarpophalangeal joint contractures are often fully correctable; however, proximal interphalangeal joint contractures often have residual deformity [36].

Multiple surgical procedures have been described for the treatment of Dupuytren contracture. Malingue's procedure is a modified Z-plasty, making use of Euclidean geometry and avoiding the use of skin grafts or flaps, and may potentially have a lower incidence of reoperation [37].

In addition, variations of subcutaneous fasciotomy, fasciectomy, and skin grafting have been used. A controlled randomized trial between the two most common approaches found no statistical difference at 2 years [38]. Fewer complications are seen with limited fasciectomy, and this is often the procedure of choice for higher risk patients, for whom temporary relief is a therapeutic goal. A diseased cord arising from the abductor digiti minimi is noted to be present in approximately 25% of cases [39], and it should be released at the time of surgery if it is present. Full-thickness skin grafting has been shown to prevent recurrence [40] and is considered in patients with a strong diathesis who have functionally limiting contracture.

Potential Disease Complications

In some individuals, the condition can become functionally limiting because of severe contracture. The thumb and index finger tend to be less affected than the other digits. Secondary contracture of the proximal interphalangeal joints can also develop in long-standing deformity. Vascular compromise is rare and more often part of complex regional pain syndrome after surgery. It appears that there is an advantage with axillary block or intravenous regional anesthesia with clonidine over lidocaine alone or general anesthesia in preventing complex regional pain syndrome in patients undergoing Dupuytren surgery [41].

Potential Treatment Complications

Overall, recurrence of the disease after surgery is common (approximately 31%) [42], which is unsurprising when one considers that surgery does not alter the underlying histopathologic process. Loss of flexion into the palm is particularly disturbing to patients. The presence of thickly calloused hands can result in increased postoperative swelling, leading to longer postoperative follow-up. "Flare reaction" is a postoperative complication in 5% to 10% of patients that occurs 3 to 4 weeks after surgery and is characterized by redness, swelling, pain, and stiffness [43]. Complication rates are higher with greater disease severity, in particular proximal interphalangeal joint flexion contracture of 60 degrees or more. Amputation and ray resections are reported complications more common in surgery for recurrences [43]. Although women with the disease less frequently meet operative

criteria, they are thought to have a higher incidence of complex regional pain syndrome postoperatively [44]. Other potential surgical complications are digital hematoma, granulation, scar contracture, inadvertent division of a digital nerve or artery, infection, and graft failure in full-thickness grafting procedures. A potential complication of injection therapy is injury to nearby structures, including the digital artery, nerve, and flexor tendons. One study [31] reported 96.6% of the patients who received collagenase to have had at least one "treatment-related" adverse event (compared with 21.2% with placebo), but care should be taken in interpreting this number as events such as "ecchymosis" and "injection-site pain" are potentially subjective, to be expected with any needle entry, and should not necessarily be attributed to the collagenase.

M20.029 Boutonnière deformity of unspecified finger(s)

Definition

Extensor tendon injuries occur to the extensor mechanism of the digits. They include the finger and the thumb extensors and abductors. These injuries are more common than flexor tendon injuries because of their superficial position and relative lack of soft tissue between them and the underlying bone. As a result, the extensor tendons are prone to laceration, abrasion, crushing, burns, and bite wounds [1]. Demographic data defining age, gender, and occupation for the development of extensor tendon injury are not well documented. However, in our clinical experience, extensor tendon injuries commonly occur from lacerations, fist to mouth injuries, and rheumatologic conditions.

Extensor tendon injuries result in the inability to extend the finger because of transection of the tendon itself, extensor lag, joint stiffness, and poor pain control [2,3]. There are eight zones to the extensor mechanism where injury can result in differing pathomechanics [4] (Fig. 30.1).

Symptoms

Patients typically lose the ability to fully extend the involved finger (Fig. 30.2). This lack of motion may be confined to a single joint or the entire digit. Pain in surrounding regions often accompanies the loss of motion because of abnormal tissue stresses. Diminished sensation may be present if there is concomitant injury to the digital nerves.

Physical Examination

Physical examination begins with observation of the resting hand position. If the extensor tendon is completely disrupted, the unsupported finger will assume a flexed posture. Range of motion, both active and passive, is evaluated for each finger joint. Grip strength is commonly measured by use of a hand-held dynamometer. Individual finger extension strength can be recorded by manual muscle testing or finger dynamometry. Sensation should be checked because of the proximity of the extensor mechanism to the digital nerves. The radial and ulnar sides of the digit should be checked to assess light touch, pinprick, and two-point discrimination.

FIGURE 30.1 Zones of extensor tendons. Odd numbers overlie the respective joints, and even numbers overlie areas of intermediate tendon regions.

FIGURE 30.2 Extensor tendon disruption of the ring finger resulting in an inability to extend the ring finger. (Modified from Daniels JM II, Zook EG, Lynch JM. *Hand and wrist injuries: part I. Nonemergent evaluation*. *Am Fam Physician* 2004;69:1941-1948.)

Functional Limitations

The positioning of the hand in preparation for grip or pinch is occasionally more important and limiting than the inability to grasp. Functional limitations therefore are manifested as the inability to produce finger extension in preparation

for grip or pinch. As a result, writing and manipulation of small objects can be problematic. Patients may also have difficulty reaching into confined areas, such as pockets, because of a flexed digit with the limited ability to extend.

Diagnostic Studies

Anteroposterior and lateral radiographs of the involved hand and fingers are obtained when there is a possibility of bone or soft tissue injury, such as fracture of a metacarpal from a bite wound, foreign body retention from glass or metal, or air in the soft tissues or joint space secondary to penetration of a foreign object. Ultrasonography is an inexpensive alternative to magnetic resonance imaging for the detection of foreign bodies and identification of traumatic lesions of tendons. However, ultrasonography and magnetic resonance imaging are generally not necessary but can be used to confirm clinical suspicion of chronic and partial extensor tendon injuries.

Differential Diagnosis

- Fracture dislocation
- Joint dislocation
- Peripheral nerve injury
- Osteoarthritis
- Rheumatoid arthritis
- Trigger finger (stenosing tenosynovitis)

Treatment

Initial

The treatment protocols for extensor tendon injuries vary by zone, mechanism, and time elapsed since the injury. If the disruption of the extensor mechanism is due to a laceration, crush injury, burn, or bite, surgical referral is warranted. In open injuries, if repair is not immediate, appropriate antibiotics should be initiated, the injured tendon should be promptly irrigated, and primary coverage by skin suturing should be performed to protect the tendon and to decrease the potential for infection. The surgeon who will be performing the definitive repair should be contacted before this, however [5]. Conservative splinting can be attempted for closed zone I and zone II extensor tendon injuries.

Rehabilitation

Conservative treatment and splinting have been recommended for zone I and zone II injuries. Conservative treatment of injuries involving zones III through VIII has limited success in restoring normal range of motion and function. Acute injuries in these zones usually require surgical repair, and chronic injuries often require surgical review.

Zone I (Mallet Deformity)

Disruption of continuity of the extensor tendon over the distal interphalangeal (DIP) joint produces the characteristic flexion deformity of the DIP joint [6]. Injury in this region is the result of a traumatic event, such as sudden forced hyperflexion of an extended DIP joint with tendinous

disruption or avulsion fracture at the site of insertion. The digits most commonly involved are the long, ring, and small fingers of the dominant hand [7]. When it is left untreated for a prolonged time, hyperextension of the proximal interphalangeal (PIP) joint (swan-neck deformity) may develop because of proximal retraction of the central band [6].

In a closed injury, the most common method of treatment is 6 weeks of continuous immobilization of the DIP joint in full extension or slight hyperextension (0 to 15 degrees) [8–12]. The DIP joint should not be immobilized in excessive hyperextension because of compromise of the vascular supply to the dorsal skin [7]. Stack splints are commonly used to achieve extension at the DIP joint. The splint should be worn continuously, except during hygiene. When the splint is removed, the DIP joint should be maintained in extension. If no extensor lag is identified after 7 weeks, range of motion exercises consisting of 10 repetitions hourly of passive, pain-free motion of the DIP joint can be initiated. The splint should be worn during exercise and at night. Splinting may be discontinued and exercises progressed to active extension after 8 weeks. In chronic mallet deformities, in which no treatment is initiated for 3 weeks after injury, splinting is recommended for 8 weeks before beginning of range of motion exercises (Table 30.1) [9,11,12].

Zone II

Injuries in zone II are often due to a laceration or crush injury. Treatment involves routine wound care and splinting for 7 to 10 days, followed by active motion if less than 50% of the tendon width is cut. If more than 50% of the tendon is cut, it should be repaired primarily, followed by 6 weeks of splinting [6].

Zone III (Boutonnière Deformity)

Zone III injuries usually result from direct forceful flexion of an extended PIP joint, laceration, or bite. If the lateral bands slip volarly, a boutonnière deformity results. The boutonnière deformity develops gradually and usually appears 10 to 14 days after the initial injury. Diagnosis is best made after splinting of the finger straight for a few days and reexamination of the finger after swelling subsides. Absent or weak active extension of the PIP joint is a positive, confirmatory finding [6].

Closed injuries are initially treated with 4 to 6 weeks of splinting of the PIP joint in extension with the metacarpophalangeal (MCP) and wrist joints left free. The splint is reapplied for recurrence of deformity [6]. Displaced closed avulsion fractures at the base of the middle phalanx, axial and lateral instability of the PIP joint with loss of joint motion, and failed nonoperative treatment are indications for surgical intervention [6]. In addition, acute open injuries require primary surgical repair.

Postoperative rehabilitation has changed in recent years with the implementation of early protected motion [8–10,13]. Postoperatively, the finger is immobilized in a PIP joint gutter splint. This splint is removed hourly to perform guarded active motion exercises, which may consist of using two exercise braces that provide optimal gliding of the extensor mechanism (Table 30.2).

Zone IV

Injuries in zone IV usually spare the lateral bands. However, there is often considerable adhesion with resultant loss of motion that develops because of the intricate relationship of the tendon and bone in this area. Rehabilitation and splinting techniques are similar to those in zone III (see Table 30.2).

Table 30.1 Zone I and Zone II Injuries

	Splint	Exercises	Wound and Skin Care
Acute DIP Joint Injuries, Mallet Deformity (Less than 3 Weeks)			
0-5 weeks	Continuous DIP joint extension (stack)	Active flexion and extension of PIP and MCP joints (hourly)	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
6 weeks	Worn between exercises and at night	Active flexion and extension of DIP joint (hourly)	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
7 weeks	Worn between exercises and at night	Passive flexion and extension of DIP joint (hourly)	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
8 weeks	If no extensor lag, may gradually wean from splint	Continue with active and passive DIP joint exercises	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
Chronic DIP Joint Injuries, Mallet Deformity (More than 3 Weeks)			
0-7 weeks	Continuous DIP joint extension (stack)	Active flexion and extension of PIP and MCP joints (hourly)	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
8 weeks	Worn between exercises and at night	Active flexion and extension of DIP joint (hourly)	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
9 weeks	Worn between exercises and at night	Passive flexion and extension of DIP joint (hourly)	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)
10 weeks	If no extensor lag, may gradually wean from splint	Continue with active and passive DIP joint exercises	Remove splint daily to check for skin integrity and hygiene (maintain DIP joint in extension)

Zone V

Zone V is located over the MCP joints. This is the most common area of extensor tendon injuries resulting from bites, lacerations, or joint dislocation [1]. The injury more often occurs with the joint in flexion, so the tendon injury will actually be proximal to the dermal injury [6]. Acute open injuries are surgically repaired after thorough irrigation if they are not the result of a human bite or fist to mouth injury.

Many authors have recently recommended that dynamic splinting be initiated in the first week [8,9,11,12,14,15]. This is accomplished with a dorsal dynamic extension splint that has stop beads on the suspension line, which limits flexion (Fig. 30.3A). Patients are instructed to perform active flexion of the fingers hourly (Fig. 30.3B). The rubber band suspension provides passive extension. Therapy is initiated early by a skilled therapist by positioning the wrist in 20 degrees of flexion and passively flexing the MCP joint to 30 degrees. This provides for safe protected gliding of the extensor mechanism. At postoperative week 7, progressive strengthening exercises can be initiated. At week 9, all bracing may be discontinued if no extensor lag is present (Table 30.3).

When the wound is associated with a human bite, it is extensively inspected and débrided; culture specimens are obtained, and the wound is irrigated and left open. Broad-spectrum antibiotics are initiated. The hand is splinted with the wrist in approximately 45 degrees of extension and the MCP joint in 15 to 20 degrees of flexion. The wound typically heals within 5 to 10 days, and secondary repair is rarely needed [6].

Zone VI

Zone VI is located over the metacarpals. Injuries to this area have a clinical picture similar to that of zone V injuries and are treated as such (see Table 30.3) [9,11,12,14,15].

Zone VII

Zone VII lies at the level of the wrist. Tendons in this region course through a fibro-osseous tunnel and are covered by the extensor retinaculum. Complete laceration of the

FIGURE 30.3 A, Splint allows 30 to 40 degrees of active MCP joint flexion with passive return to neutral. B, Flexion is limited by stop beads on the outrigger strings.

tendons in this region is rare. Tendon retraction can be a significant problem in this region, and primary repair is warranted, with preservation of a portion of the retinaculum to prevent extensor bowstringing [6]. Rehabilitation is similar to that in zone V (see Table 30.3).

Zone VIII

Zone VIII lies at the level of the distal forearm. Multiple tendons may be injured in this area, making it difficult to

Table 30.3 Zone V, Zone VI, and Zone VII Injuries

	Splint	Exercises	Wound and Skin Care
Start 24-48 hours	Dorsal dynamic extension splint (see Fig. 30.3) Night splint: MCP joint	Exercise hourly in extension splint: allows 30-40 degrees of MCP joint flexion With skilled therapist: wrist at 20 degrees, passive MCP joint flexion to 30 degrees; patient performs active extension (daily to 3 times a week)	Daily removal of splint for wound cleaning Edema control with 0-3 compressive wrap
4 weeks	Continue with dynamic day splint, static night splint	Increase active range of motion to 50-60 degrees	Daily removal of splint for wound cleaning Edema control with 0-3 compressive wrap
5 weeks	Discontinue dynamic extension splint MCP joint block splint worn at night and between exercises	Increase active range of motion exercises to full motion	Daily removal of splint for wound cleaning Edema control with 0-3 compressive wrap
6 weeks	MCP joint block splint	Passive flexion exercises of MCP and IP joints (buddy tape)	Daily removal of splint for wound cleaning Edema control with 0-3 compressive wrap
7 weeks	MCP joint block splint	Progressive extension exercises, with mild resistance	Daily removal of splint for wound cleaning Edema control with 0-3 compressive wrap
9 weeks	If no extensor lag, discontinue all splints	Continue with active and passive DIP joint exercises	Daily removal of splint for wound cleaning Edema control with 0-3 compressive wrap

identify individual tendons. Restoration of independent wrist and thumb extension should be given priority [6]. Injuries in this location often require tendon retrieval for complete lacerations, and surgical intervention is warranted.

Postoperative rehabilitation consists of static immobilization of the wrist in 45 degrees of extension with the MCP joints in 15 to 20 degrees of flexion. Splinting is generally maintained for 4 to 5 weeks. However, early controlled motion with a dynamic extensor splint may help decrease adhesions and subsequent contractures. Dynamic motion of the MCP joints may be started at 2 weeks.

Procedures

Surgical repair is the mainstay for treatment of most extensor tendon injuries. Injections are typically not appropriate for the management of these conditions.

Surgery

Zone I and zone II injuries are typically treated nonoperatively, unless there is laceration of the terminal extensor slip (zone II injury), which may then require surgical repair. Surgical correction of zone I and zone II injuries usually results from failed conservative bracing, usually in a younger patient. In addition, patients may elect to have the terminal extensor tendon repaired or the DIP joint fused for cosmetic reasons. In older individuals with fixed deformities and painful arthritic conditions that limit function, joint arthrodesis is a reasonable approach.

Surgical intervention in zones III through VIII is usually primary repair of the injured extensor tendon mechanism. If primary repair is not possible, tendon grafting has been described [4,16].

Potential Disease Complications

Extensor tendon injury can result in permanent loss of finger extension, primarily due to adhesion formation or joint contracture. Painful degeneration of the affected joints can occur if normal motion is not restored.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, renal, and cardiovascular systems. Acute tendon ruptures as a result of aggressive therapy necessitate reoperation, which may include tendon grafting. Therapy programs that are not aggressive enough often result in reduced range of motion and strength. Surgical complications include infection, adhesion formation, and advanced joint degeneration.

Flexor Tendon Injuries

Jeffrey S. Brault, DO

Synonyms

Flexor tendon injury, laceration, or rupture
Jersey or sweater finger

ICD-9 Codes

- 727.64 Rupture of flexor tendons of hand and wrist, nontraumatic
- 842.1 Sprains and strains of the wrist and hand, unspecified site
- 848.9 Lacerated tendon (not specific to the hand)

ICD-10 Codes

- M66.341 Spontaneous rupture of flexor tendons, right hand
- M66.342 Spontaneous rupture of flexor tendons, left hand
- M66.349 Spontaneous rupture of flexor tendons, unspecified hand
- S63.90 Sprain of unspecified part of unspecified wrist and hand
- S63.91 Sprain of unspecified part of right wrist and hand
- S63.92 Sprain of unspecified part of left wrist and hand
- The appropriate seventh character is added to each code of category 63 to determine episode of care.
- S66.921 Laceration of unspecified muscle, fascia and tendon at wrist and hand level, right hand
- S66.922 Laceration of unspecified muscle, fascia and tendon at wrist and hand level, left hand

S66.929 Laceration of unspecified muscle, fascia and tendon at wrist and hand level, unspecified hand

The appropriate seventh character is added to each code of category 66 to determine episode of care.

Definition

The flexor tendons of the hand are vulnerable to laceration and rupture. These injuries are most commonly seen in individuals who work around moving equipment, use knives, or wash glass dishes; in people with rheumatoid arthritis; and in athletes (jersey finger) [1]. The flexor digitorum profundus (FDP) of the ring finger is the most commonly involved [2]. Incomplete injuries to the flexor tendon are easily missed on physical examination and can progress to full ruptures.

Regions of potential tendon injury are divided into five zones (Fig. 31.1) [3]. Zone I is from the tendon insertion at the base of the distal phalanx to the midportion of the middle phalanx. Laceration or injury in this zone results in disruption of the FDP tendon and the inability to flex the distal interphalangeal (DIP) joint. Zone II extends from the midportion of the middle phalanx to the distal palmar crease. This zone is known as no man's land because of the poor functional results after tendon repair [4,5]. Tendon injury in this zone usually involves both FDP and flexor digitorum superficialis (FDS) tendons and results in inability to flex the DIP and proximal interphalangeal (PIP) joints. Zone III is located from the distal palmar crease to the distal portion of the transverse carpal ligament. This zone includes the intrinsic hand muscles and vascular arches. Zone IV overlies the transverse carpal ligament in the area of the carpal tunnel. In this zone, injuries usually involve multiple FDP and FDS tendons. Zone V extends from the wrist crease to the level of the musculotendinous junction of the flexor tendons. Injuries in this region most often result from self-inflicted laceration (suicide attempts).

The flexor tendons are held close to the bone in zone I and zone II by a complex series of pulleys and vincula. These structures are frequently injured with the tendons [1].

FIGURE 31.1 Zones of flexor tendons.

Symptoms

On occasion, individuals may hear a popping sensation as the flexor tendon tears. This is followed by pain, swelling, and inability to flex the affected joint. Sensation of the involved finger is often affected because of the proximity of the flexor tendons to the neurovascular bundle.

Physical Examination

Obtaining a detailed history is important to outline the mechanism of injury. Evaluation begins with observation of the resting hand position. If the flexor tendon is completely severed, the unsupported finger will assume an extended position (Fig. 31.2) [1,6]. Active flexion of all finger joints needs to be assessed. If active finger flexion is not observed because of pain, tenodesis can be employed to determine whether the tendon is intact. The wrist is passively extended, and all fingers should assume a relatively flexed posture. If the flexor tendons are disrupted, the finger will remain in a relatively extended posture.

Flexion strength of each digit should be evaluated by manual muscle testing or finger dynamometry. Strength is evaluated by having the patient individually flex first the DIP joint and then the PIP joint against applied resistance. It is possible to have a complete laceration of the flexor tendons with preservation of peritendinous structures and active motion. In these cases, however, flexion will be weak [7].

FIGURE 31.2 Jersey finger. The flexor profundus tendon is detached by a forced hyperextension of the DIP joint. (Reprinted from Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

For individual function of the FDP tendon to be checked, the patient is asked to flex the fingertip at the DIP joint while the PIP joint is maintained in extension. If there is injury to the FDP tendon, the patient will be unable to flex the DIP joint.

It is difficult to diagnose solitary injuries of the FDS tendon because of the FDP tendon's ability to perform flexion of all finger joints through intertendinous connections. For the integrity of the FDS tendon to be isolated, all the fingers are held straight, placing the FDP tendon in a biomechanically disadvantaged position. The patient actively attempts to flex the finger to be tested while the other fingers are held in relative extension. If the patient is unable to move the finger, injury most likely has occurred to the FDS tendon. This test is reliable only for the middle, ring, and small fingers.

Sensation of the finger should be evaluated because open tendon injuries often are accompanied by injuries of the nearby digital nerves. Two-point discrimination of radial and ulnar aspects of the digit should be assessed before injection of local anesthetic for wound care [1].

Functional Limitations

Functional limitations include difficulty with power grasp if the ulnarly sided tendons are involved and precision grasp problems if the radially sided tendons are involved. The patient may present with inability to button shirts, to pinch small objects, or to firmly grasp objects.

Diagnostic Studies

Radiographic evaluation includes anteroposterior and lateral views of the involved fingers. These assist in identification of joint dislocation, articular disruption, avulsion, long

bone fractures, and potential for retained foreign bodies. Ultrasonography and magnetic resonance imaging are used to identify partially lacerated or ruptured tendons. Ultrasound provides dynamic studies of the tendons.

Differential Diagnosis

Partial tendon laceration
Anterior interosseous nerve injury
Trigger finger (stenosing tenosynovitis)
Median nerve injury

Treatment

Initial

Surgical intervention is almost always required for flexor tendon injuries [1,7]. Protection of the affected finger in a bulky dressing and meticulous wound care are recommended before surgical correction.

Cleaning and repair of superficial wounds should be performed if surgical referral is delayed. Optimally, surgical correction of the flexor tendon injury occurs within the first 12 to 24 hours. Delayed primary repair is performed in the first 10 days. If primary repair is not performed because of infection, secondary repair can be performed up to 4 weeks. If repair is not performed within 4 weeks, the tendon usually is retracted within the sheath, making surgical repair difficult [7].

Newer surgical repair and suture techniques have improved the strength of repaired flexor tendons, providing for earlier rehabilitation [7–9].

Rehabilitation

Postoperative rehabilitation of repaired tendons has changed greatly in the past three decades through initiation of early protected motion [10–14]. Historically, the repaired fingers were placed in an immobilization splint for up to 2 months.

This often led to adhesion formation and ultimately the loss of motion and function [12].

The currently accepted rehabilitation schemes for repaired flexor tendons are essentially the same for all zones (Table 31.1).

Immediately postoperatively, the hand is placed in a protective dorsal splint with 20 to 30 degrees of wrist flexion. All metacarpophalangeal (MCP) joints are placed in 20 to 50 degrees of flexion, depending on zone [13–15]. A dorsal hood extends to the fingertip level, allowing PIP joint and DIP joint extension to 0 degrees. All of the fingers are held in flexion by dynamic traction applied by rubber bands originating from the proximal forearm with a pulley at the palm and attachment to the fingernails (Fig. 31.3A).

The patient is typically seen by the therapist 24 to 48 hours after surgical repair. Dressings are changed, and rehabilitation goals are discussed [12–14]. The patient is instructed to actively extend the fingers against the rubber band traction to the dorsal block, 10 repetitions hourly, to prevent flexion contractures (see Fig. 31.3B). The rubber band traction passively returns the fingers to a flexed position. At night, the traction is removed and the fingers are strapped to the dorsal hood with the PIP and DIP joints in extension.

The rehabilitation program may involve immediate short arc motion [12,13,16,17]. Under the supervision of a skilled therapist, the injured digit is placed in moderate flexion with the wrist in 30 to 40 degrees of extension, the MCP joints in 80 degrees of flexion, the PIP joints in 75 degrees of flexion, and the DIP joints in 30 to 40 degrees of flexion. The patient is then instructed to actively hold this position for 10 seconds. On completion of the static contraction, the therapist passively flexes the wrist. This allows natural tenodesis to extend the fingers. At day 21, the patient can initiate unsupervised active flexion exercises. At 35 days, the dorsal digital splint is removed and active tendon gliding exercises are initiated [12,14,15,17,18].

Modalities such as ultrasound, contrast or paraffin baths, whirlpool, and fluidized therapy may be used to promote wound healing and range of motion in the latter stages of therapy.

Table 31.1 Flexor Tendon Injuries (Immediate Motion)

	Splint	Exercises	Wound and Skin Care
Postoperatively to 21 days	Postoperative dynamic flexion splint with dorsal hood (see Fig. 31.3) Wrist flexion at 20–30 degrees MCP joint, 20–50 degrees; PIP and DIP joints, 0 degrees of extension	Patient actively extends each finger 10 times hourly (start postoperative day 2) Under the direction of a hand therapist, wrist flexion is used to produce less tension on the flexor tendon during passive exercises Initiate supervised active flexion exercises (postoperative day 14)	Daily removal of splint for wound cleaning Edema control with compressive wrap
21–35 days	Progressive reduction in use of splint	Patient may begin to perform active flexion exercises without therapist	Continue with wound care and edema control as needed
35 days	Discontinue splint	Progress to increased active and passive flexion exercises; grip strengthening	Continue with wound care and edema control as needed

FIGURE 31.3 A, Dorsal dynamic protection splint; fingers in resting position. B, Dorsal dynamic protection splint; active extension exercises.

Procedures

Procedures are generally not indicated in flexor tendon injuries. Wound care is paramount to prevent infections of surgical incisions. Corticosteroid injections can be performed if stenosing tenosynovitis (triggering) develops at the flexor pulleys.

Surgery

Optimally, repair of the flexion tendon should occur within the first 48 hours after injury. Improper handling of tissues during repair can result in hematoma, damage to the pulley integrity, and damage to the vincula—the vascular supply of the tendons [19].

Potential Disease Complications

Injury to the flexor tendon mechanism can result in permanent loss of finger flexion. Partial tendon damage can easily be missed and result in either weakness or complete rupture.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the

gastric, hepatic, and renal systems. Postsurgical complications include adhesion formation and tendon rupture. Postsurgical tendon rupture is usually the result of aggressive motion, by either the patient or therapist, that results in failure of the repair. Reoperation is often required, which results in the greater propensity for adhesion formation. Adhesion formation and the loss of motion and strength complicate surgical repair, particularly in zone II [4,5].

Many other factors affect healing of the tendon and postoperative rehabilitation. Factors such as advanced age, poor circulation, tobacco and caffeine use, and generalized poor health can contribute to impaired healing. Scar formation can result in adhesion formation and decreased movement. Poor motivation and compliance with the therapy program result in less than optimal recovery.

Intraosseous cyst

ICD-9 Codes

727.41 Ganglion of joint
727.42 Ganglion of tendon sheath

ICD-10 Codes

M67.40 Ganglion of joint, unspecified site
M67.40 Ganglion of tenon sheath

Definition

Hand and wrist ganglia account for 50% to 70% of all hand masses. The ganglion is a benign, mucin-filled cyst found in relation to a joint, ligament, or tendon. It is typically filled from the joint through a tortuous duct or “stalk” that functions as a valve directing the flow of fluid. The mucin itself contains high concentrations of hyaluronic acid as well as glucosamine, albumin, and globulin [1]. When it is used to describe ganglia, the term *synovial cyst* is actually a misnomer because ganglion cysts do not contain synovial fluid and are not true cysts lined by epithelium but rather by flat cells. The etiology of ganglia remains a mystery, although many think that ligamentous degeneration or trauma plays an important role [1,2].

By far, the most common location for a ganglion is the dorsal wrist (Fig. 32.1), with the pedicle arising from the scapholunate ligament in virtually all cases. Only 20% of ganglia are found on the volar wrist (Fig. 32.2). This type may originate from either the radioscaphoid or scaphotrapezoid joint. Alternatively, ganglia can occur near the joints of

the finger. One subtype of hand-wrist ganglia is the “occult” cyst, which is not palpable on physical examination.

Ganglion cysts occur more commonly in women, usually between the ages of 20 and 30 years. However, they can develop in either sex at any age. Ganglia of childhood usually resolve spontaneously during the course of 1 year [3]. The most commonly seen ganglion of the elderly, the mucous cyst, arises from an arthritic distal interphalangeal joint (Fig. 32.3).

Other common types of ganglia in the hand include the retinacular cyst (flexor tendon sheath ganglion; Fig. 32.4), proximal interphalangeal joint ganglion, and first extensor compartment cyst associated with de Quervain tenosynovitis. Less common ganglia include cysts within the extensor tendons or carpal bones (intraosseous) and those associated with a second or third carpometacarpal boss (arthritic spur). Rarely, ganglia within the carpal tunnel or Guyon canal can produce carpal tunnel syndrome or ulnar neuropathy, respectively.

As noted, the cause of ganglion cyst formation is not known, but there may be a link to light, repetitive activity, demonstrated by an increased incidence in typists, musicians, and draftsmen. Interestingly, there is no increased risk in heavy laborers, who bear a greater load on their wrists. Wrist instability has also been discussed as both a possible cause and an effect of the disease. Overall, there is a history of trauma in 10% to 30% of people presenting with the disease [2].

Symptoms

Patients with a wrist ganglion usually present with a painless wrist or hand mass of variable duration. The cyst may fluctuate in size or disappear altogether for a time. Pain and weakness of grip are occasional presenting symptoms; however, an underlying concern about the appearance or seriousness of the problem is usually the reason for seeking medical attention. The pain, when present, is most often described as aching and aggravated by certain motions. With dorsal wrist ganglia, patients often complain of discomfort as the wrist is forcefully extended (e.g., when pushing up from a chair). Interestingly, dorsal wrist pain may be the principal complaint of patients with an occult dorsal wrist ganglion, which is not readily visible. The wrist pain usually subsides as the mass enlarges.

FIGURE 32.1 Dorsal wrist ganglion. The mass is typically found overlying the scapholunate area in the center of the wrist.

FIGURE 32.2 Clinical appearance of a volar wrist ganglion.

FIGURE 32.3 Mucous cyst. This ganglion originates from the distal interphalangeal joint. Pressure on the nail matrix by the cyst may produce flattening of the nail plate, as is seen here.

FIGURE 32.4 Retinacular cyst. This ganglion originates from the flexor tendon sheath.

With a retinacular cyst, patients usually complain of slight discomfort when gripping, for example, a racket handle or shopping cart. Patients whose complaints of pain are primarily related to de Quervain tenosynovitis (see Chapter 28) may notice a bump over the radial styloid area. Pain with grip is also a complaint of patients with a carpometacarpal boss. On occasion, the digital extensor tendons may jump over the cyst with radioulnar deviation. Mucous cysts can drain spontaneously and can also produce nail deformity, either of which may be a presenting complaint. Symptoms identical to those of carpal tunnel syndrome will be noted by patients with a carpal tunnel ganglion. A ganglion in the Guyon canal will produce hand weakness (due to loss of intrinsic function) and may produce numbness in the ring and small fingers.

Physical Examination

Ganglia are typically solitary cysts, although they are often found to be multiloculated on surgical exploration. They are usually mobile a few millimeters in all directions on physical examination. The mass may be slightly tender. When the cyst is large, transillumination (placing a penlight directly onto the skin overlying the mass) will help differentiate it from a solid tumor.

The classic location for a dorsal wrist ganglion is ulnar to the extensor pollicis longus, between the third and fourth tendon compartments, or directly over the scapholunate ligament [1]. However, these ganglia may have a long pedicle that courses through various tendon compartments and exits at different locations on the dorsal wrist or even the volar wrist. When the ganglion is small, it may be apparent only with wrist flexion. Wrist extension and grip strength may be slightly diminished. Dorsal wrist pain and tenderness with no obvious mass or instability should suggest an occult ganglion.

Volar ganglia occur most commonly at the wrist flexion crease on the radial side of the flexor carpi radialis tendon but may extend into the palm or proximally, or even dorsally, into the carpal tunnel. They can involve the radial artery, complicating their surgical removal. They may seem to be pulsatile, although careful inspection will demonstrate that the radial artery is draped over the mass.

FIGURE 32.5 The Allen test is performed by asking the patient to open and close the hand several times as quickly as possible and then to make a tight fist (A). The examiner then compresses the radial and ulnar arteries as the hand is opened (B). One artery is tested by releasing the pressure over the artery to see whether the hand flushes (C). The other artery is tested in a similar fashion, and the opposite hand is tested for comparison.

Retinacular cysts are usually not visible but are palpable as pea-sized masses, typically located at the volar aspect of the digit at the palmar digital crease. They are adherent to the flexor tendon sheath and do not move with finger flexion. Alternatively, intratendinous ganglia are distinguished by the fact that they move with finger motion.

Mucous cysts are located over the distal interphalangeal joint, and the overlying skin may be quite thin. They are occasionally mistaken for warts. Spontaneous drainage and even septic distal interphalangeal joint arthritis are not uncommon. Nail plate deformity is an associated finding. Proximal interphalangeal joint ganglia are located on the dorsum of the digit, slightly off midline. Ganglia associated with carpometacarpal bosses produce tender prominences on the dorsum of the hand distal to the typical location for a wrist ganglion.

An important sign to look for on physical examination, especially in planning for surgery, is compression of the median or ulnar nerve or of the radial artery. An Allen test should be performed before surgery to evaluate radial and ulnar artery patency, particularly in the case of a volar cyst (Fig. 32.5).

Functional Limitations

Physical limitations due to ganglion cysts are rare. With dorsal wrist ganglia, fatigue and weakness are occasional findings. Patients may have difficulty with weight bearing on the affected extremity with the wrist extended (e.g., when pushing up from a chair).

Diagnostic Studies

The diagnosis of a ganglion cyst is usually straightforward, and ancillary studies are often unnecessary. With wrist ganglia, plain radiographs of the wrist are usually obtained preoperatively to evaluate the carpal relationships and to

exclude the possibility of an intraosseous ganglion. With a mucous cyst, radiographs of the affected digit will usually demonstrate a distal interphalangeal joint osteophyte. Ultrasonography or magnetic resonance imaging may be useful in identifying deep cysts in cases of vague dorsal wrist pain. Specifically, magnetic resonance imaging is indicated to rule out Kienböck disease in patients with dorsal wrist pain and no obvious ganglion or wrist instability. In hand soft tissue masses when magnetic resonance imaging is nondiagnostic, the most common underlying diagnoses include giant cell tumor of tendon sheath, angioleiomyoma, fibroma, and peripheral nerve sheath tumor [4]. Cyst aspiration is the single best confirmatory study for ganglion. Aspiration characteristically yields a viscous, clear to yellowish fluid with the appearance and consistency of apple jelly. On occasion, the fluid will be blood tinged.

Differential Diagnosis

WRIST

- Carpal boss
- Extensor tenosynovitis
- Wrist synovitis
- Scapholunate ligament injury or sprain
- Kienböck disease (avascular necrosis of the lunate)
- Lipoma

DIGITS

- Giant cell tumor of tendon sheath
- Hemangioma
- Angioleiomyoma
- Peripheral nerve sheath tumor
- Fibroma
- Synovitis

Treatment

Initial

Reassurance is the single most important initial treatment. Many patients are satisfied to know that they do not have a serious illness. It is important to tell patients that the cyst often fluctuates in size and occasionally disappears on its own. Undoubtedly, observation is the most appropriate treatment of ganglia in children, as long as the diagnosis is certain. In adults, splinting is an appropriate initial treatment of cysts associated with discomfort. A cock-up wrist splint is prescribed for carpometacarpal and dorsal and volar wrist ganglia, whereas a radial gutter splint is prescribed for ganglia associated with de Quervain tenosynovitis. Traditional methods of crushing the cyst with a coin or a Bible, even though occasionally successful, are not recommended. Anecdotally, daily massage of mucous cysts by patients may be successful in resolving them as long as the overlying skin is healthy. Analgesics or nonsteroidal anti-inflammatory drugs may be used on a limited basis for discomfort but do little to treat the disorder.

Rehabilitation

Rehabilitation has a role primarily in the postsurgical setting. The usual course of treatment after dorsal ganglion excision involves 7 to 14 days of immobilization in slight wrist flexion to minimize loss of wrist flexion secondary to scarring. Frequent, active range of motion of the wrist should be started after splint removal, and the patient should be able to return to relatively normal activity approximately 3 weeks after surgery [1]. Most patients are able to carry out their own rehabilitation at home. Formal therapy can be ordered if patients have difficulty returning to normal functioning. Therapy may include modalities for pain control, active-assisted and passive range of motion exercises, and strengthening exercises. Therapists may also evaluate return to work issues, including adaptive equipment that may assist patients in their daily work functions.

Procedures

Aspiration of the cyst serves two purposes: it confirms the diagnosis, and it may be therapeutic. Unfortunately, the recurrence rate after ganglion aspiration is high. One study [5] demonstrated long-term success rates of 27% and 43% for dorsal and volar wrist ganglia, respectively, treated with aspiration, multiple puncture, and 3 weeks of immobilization. Importantly, cysts present for longer than 6 months almost uniformly recurred. The results for aspiration of retinacular cysts were somewhat better, averaging 69% successful.

However, a significant number of patients may elect to proceed with cyst aspiration despite the high likelihood of recurrence. Aspiration of volar wrist ganglia may cause displacement of the cyst and envelop the radial artery. Aspiration of proximal interphalangeal joint ganglia may be successful in eliminating the cyst [6]. Aspiration of mucous cysts is not recommended.

Steroids have not been shown to add any therapeutic benefit to ganglia aspiration.

Surgery

Many patients opt for surgical excision of the cyst, often for primarily cosmetic reasons. Surgery should be advised when the diagnosis is unclear. To minimize the likelihood of recurrence, the surgeon should not only remove the cyst but trace the stalk to its origin within the joint. For wrist ganglia, the surgeon often finds that the visible mass grossly underestimates its actual size and extent. Because these procedures require opening of the wrist joint, they cannot be performed with the use of local anesthesia. With proper technique, recurrence rates should be less than 5%. Volar ganglia are more difficult to access and more often variable in their shape and location, making for more complicated surgery. A prospective cohort study of volar wrist ganglion treatment by observation, aspiration, or surgery concluded that at 5 years, there were no significant differences in the recurrence rates with any of the treatments; 42% of the excised ganglia recurred, whereas 51% of the untreated ganglia had resolved spontaneously [7]. Clearly, it is important that the risks and benefits of surgical treatment of ganglion cysts be carefully discussed with the patient.

Arthroscopic resection of dorsal wrist ganglia has been advocated to be a safe and reliable procedure, with recurrence rates of less than 5% [8]. A small case series of arthroscopic débridement of volar wrist ganglia has demonstrated excellent results as well [9].

The surgical management of mucous cysts must include excision of the cyst stalk as well as the offending osteophyte, which originates from either the dorsal base of the distal phalanx or the head of the middle phalanx. The nail deformity should resolve during several months [10].

Potential Disease Complications

Chronic wrist pain as the result of an untreated wrist ganglion is rare. The cosmetic deformity, however, is obvious. The most important complication associated with a neglected cyst is septic arthritis of the distal interphalangeal joint resulting from spontaneous drainage of a mucous cyst. For that reason, we recommend mucous cyst excision when the overlying skin is thin or spontaneous drainage has occurred.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. The patient must understand that surgery will replace a bump with a scar. Slight limitation of wrist flexion after dorsal ganglion excision is not uncommon. Another risk is iatrogenic injury to the scapholunate ligament, extensor tendon, and cutaneous nerve. Recurrence is another possibility.

Surgery performed on the volar wrist carries a greater risk of injury to artery and nerve. The structures most at risk are the palmar cutaneous branch of the median nerve and the terminal branches of the lateral antebrachial cutaneous nerve as well as the radial artery, which is often intertwined with the cyst. Perhaps because of the more intricate nature of its surgical removal, the volar cyst is associated with a higher rate of recurrence after surgery.

Definition

Osteoarthritis of the hand is a degenerative condition of hyaline cartilage in diarthrodial joints. It is distinct from inflammatory arthropathies, such as rheumatoid arthritis, in which the primary component is an inflammatory or systemic pathophysiologic process. Idiopathic osteoarthritis excludes post-traumatic arthritis or arthritic conditions resulting from pyrophosphate deposition disease, infection,

or other known causes. It is associated with aging, but variations in onset and severity seem genetically determined [1]. In particular, the early onset of osteoarthritis of the distal interphalangeal and trapeziometacarpal joints is genetically mediated separate from osteoarthritis at other joints; in other words, a 50-year-old person with severe hand arthritis is not at risk for early hip arthritis. The prevalence of osteoarthritis of the hand increases with age and is more common in men than in women until menopause. In individuals older than 65 years, osteoarthritis of the hand has been estimated to be as high as 78% in men and 99% in women [2]. The distal interphalangeal and proximal interphalangeal joints and the base of the thumb are the most affected joints.

Symptoms

Patients typically report pain, stiffness, and disability. Symptoms follow a waxing and waning course as the disease gradually and inevitably progresses. The correlation between radiographic findings and pain intensity and magnitude of disability is limited, most likely as a reflection of the psychosocial factors that mediate the difference between disease and illness and between impairment and disability. Psychological distress and ineffective coping strategies should be identified and addressed.

Physical Examination

Osteoarthritis is insidious. Although a joint “goes gray” during decades, patients often notice an acute onset of symptoms that can make it difficult for them to believe their problem is an expected slow deterioration. The hallmarks of physical examination are deformity, restriction of motion, pain, and crepitation. A careful examination of all of the joints notes any deformity, effusions, erythema, limitations in range of motion, and swelling. The findings on neurologic examination should be normal.

Interphalangeal Joints

Osteoarthritis of the distal interphalangeal joint is characterized by enlargement of the distal joint by osteophytes, forming the so-called Heberden node (Fig. 33.1). Angular and rotatory deformities of the terminal phalanx can develop (Fig. 33.2). Ganglion (or mucous) cysts are associated with osteoarthritis of the distal (and less commonly the proximal) interphalangeal joints. The pressure of these cysts on the germinal matrix can cause a groove in the fingernail. The proximal interphalangeal joint is less commonly

FIGURE 33.1 Patients with degenerative joint disease of the hands can present with Heberden nodes (*arrows*). These nodules represent osteophytes at the distal interphalangeal joint. (From Concannon MJ. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

FIGURE 33.2 Severe osteoarthritis at the distal interphalangeal joint of the fifth finger. Osteophyte formation, joint destruction, and angulation are demonstrated. (From Concannon MJ. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

involved than the distal joint. The enlargement and deformity at the proximal interphalangeal joint is referred to as a Bouchard node.

Metacarpophalangeal Joints

It is relatively uncommon for the metacarpophalangeal joints to be involved in primary idiopathic osteoarthritis. The presentation at this joint is usually characterized by complaints of pain and stiffness rather than deformity.

Trapeziometacarpal Joint

Arthritis of the trapeziometacarpal joint is associated with aging. Among women aged 80 years and older, 94% have radiographic signs of arthritis; two thirds of these have severe joint destruction [3]. Men develop arthritis more slowly than women do, but by the age of 80 years, 85% have arthritis. The process progresses from subluxation and slight narrowing

of the joint to osteophyte formation, deformity, and destruction of the joint [4]. As the disease progresses, the base of the metacarpal subluxates radially, there is an adduction contracture of the metacarpal toward the palm, and laxity and hyperextension of the metacarpophalangeal joint develop in compensation. Axial compression and rotation and shear (the compression test) will produce crepitation and reproduce symptoms [5,6]. Both active and passive movement is restricted. Grip and pinch strength gradually diminish. It is useful to screen for carpal tunnel syndrome and trigger thumb, both of which are common in this age group.

Functional Limitations

The classic forms of reported disability are activities that require a forceful grasp, such as opening a tight jar, turning a key, or opening a doorknob. Whereas fine motor tasks are often impaired by interphalangeal osteoarthritis, complaints of disability are far less common; perhaps because the disease is so gradual, most patients adapt.

Diagnostic Studies

Radiographs are rarely necessary to establish a diagnosis or to guide treatment; their chief use is for ruling out other pathologic processes and increasing the patient's understanding and acceptance of the disease process. Characteristic findings are joint space narrowing, subchondral sclerosis, osteophyte formation, and degenerative cyst formation in the subchondral bone. Eaton and Littler classified trapeziometacarpal arthritis into four radiographic stages [7]. In stage I, the articular contours are normal with no subluxation or joint debris. The joint space may be widened if an effusion is present. In stage II, there is slight narrowing of the thumb trapezial metacarpal joint, but the joint space and articular contours are preserved. Joint debris is less than 2mm and may be present. In stage III, there is significant trapezial metacarpal joint destruction with sclerotic resistive changes and subchondral bone with osteophytes larger than 2mm. Stage IV is characterized by pantrapezial arthritis in which both the trapezial metacarpal and scaphoid trapezial joints are affected.

Differential Diagnosis

- Post-traumatic arthritis
- Inflammatory arthritis (e.g., Lyme disease, gout, rheumatoid arthritis, psoriatic arthritis)
- Calcium pyrophosphate deposition disease
- Septic arthritis
- Systemic lupus erythematosus
- Scleroderma

Treatment

Initial

There are no proved disease-modifying treatments of osteoarthritis. All treatments take the form of either palliation (management) or salvage (e.g., arthrodesis or arthroplasty). Because osteoarthritis is so common (as people age, they all

have some evidence of osteoarthritis to some degree) and at least annoying if not disabling, there is extensive marketing that suggests the disease can be modified, but there is no proof of this assertion. There is also no proof that exercise or activity accelerates osteoarthritis. Exercise and activity can improve muscle strength, proprioception, and range of motion. Physicians should be cautious about advising activity restriction because it can directly create or exacerbate disability in a patient who associates pain with joint damage. Activity restriction is a personal choice determined by desired comfort level; it is entirely appropriate to remain active in spite of painful, degenerated joints.

Non-narcotic analgesics (acetaminophen and nonsteroidal anti-inflammatory medications) are useful for pain relief and safe enough for routine use in most patients. Some patients find ice, heat, or topical creams useful. Splints that immobilize arthritic joints (for instance, a hand-based thumb spica with the interphalangeal joint free for trapeziometacarpal arthritis) can provide symptomatic relief, but it must be made clear to the patient that they will not cure the disease or prevent progression by wearing them and that splint wear is optional. The interphalangeal joints are rarely splinted because of the associated functional limitations as well as infrequent requests by patients. Intra-articular injections of corticosteroids or hyaluronate [8] inconsistently provide temporary relief, but patients need to understand that these injections cannot cure the disease and that they must either cultivate effective coping mechanisms or elect salvage reconstructive surgery.

Rehabilitation

Patients can be taught alternative ways to perform tasks that are hindered by arthritis (Table 33.1). For instance, they can get a device that helps them open jars and a larger grip for pens and pencils; they can change their doorknobs to levers. Prefabricated and custom hand- or forearm-based thumb spica splints can diminish the pain of trapeziometacarpal arthritis and may be most useful during certain tasks. Therapeutic modalities such as paraffin baths may be beneficial for some people. Contrast baths and ice massage are economical modalities that may provide some relief.

Minimal supervision is needed after simple trapeziectomy. Patients are allowed activities as tolerated, and motion returns with normal use over time. If the joint is

immobilized with a Kirschner wire or ligament reconstruction is performed, the joint is protected in a cast or splint for at least 1 month. If the hand gets stiff, patients are instructed in active, self-assisted stretching exercises. Distal interphalangeal joint arthrodesis is protected with splinting until healing is apparent. Proximal interphalangeal joint arthroplasties start motion exercises as comfort allows with protection of healing ligaments as necessary.

Procedures

At best, an intra-articular injection of corticosteroids or hyaluronate will provide a few months of relief [9]. Serious complications, such as infection, are rare. The worst aspect of an injection is the disappointment felt by patients when their hoped-for miracle cure is not forthcoming or when the helpful injection (be it placebo or otherwise [10]) wears off after a few weeks to months. When the role of injections is accurately described, patients can make an informed decision. In my experience, patients do not find them very appealing. The number of corticosteroid injections at a single site is limited by the potential for skin discoloration, subcutaneous atrophy, and capillary fragility. I will not give more than three lifetime injections in the same area (Fig. 33.3).

Under sterile conditions, with use of a 25- to 27-gauge needle and a mixture of local anesthetic (e.g., 0.5 to 1 mL of 1% lidocaine) and corticosteroid (e.g., 0.5 to 1 mL of triamcinolone), the joint is injected. Small joints of the hand will not accommodate large volumes, so the total amount of fluid injected should typically be in the range of 1 to 2 mL. It is helpful to distract the joint by pulling on the finger.

Surgery

Osteoarthritis of the hand is a part of human development that all of us will experience if we are lucky to live long enough. Given the prevalence of arthritis, it is probably safe to assume that most patients adapt well to their arthritis, have effective coping skills, and never bring the arthritis to the attention of a physician. Among those who do bring the problem to a physician's attention, most are satisfied with an explanation of the disease process, the reassurance that it is normal and inevitable, an understanding that the disease cannot yet be modified, and suggestions for management

Table 33.1 Basic Principles of Arthritis Management

Understand pain	The pain does not reflect ongoing harm; it is the result of the existing, permanent disease process. Any rest or activity restriction is voluntary and intended to diminish pain. Patients should be encouraged to continue in painful activities that they value without feeling guilty, neglectful, or irresponsible.
Modify activities	Patients can be taught alternative, less painful, and easier ways to accomplish daily tasks that do not rely on painful joints. Jar openers, pen grips, and door levers rather than knobs can be useful modifications.
Maintain strength and range of motion	Patients are encouraged to continue both daily activities and sports and exercise as a means for preserving active range of motion and muscle conditioning. Daily activities may be supplemented with active range of motion exercises targeted for specific joints.
Use stronger muscles and larger joints	In addition, the patient can be taught to carry items close to the body or to cradle them in the entire arm to distribute loads, rather than relying on smaller muscles and joints of the hand to bear the entire load.
Use adaptive equipment or splints	The patient is provided with information on specific adaptive devices that are helpful in reducing or eliminating positions of deformity or stress on the smaller joints. Splints can be useful for limiting pain with specific activities.

FIGURE 33.3 A, Needle placement into the carpometacarpal joint. B, Anteroposterior radiograph of the hand demonstrating needle placement into the first carpometacarpal joint. C, Needle placement into the interphalangeal joint. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

and palliation. Surgery provides fairly predictable pain relief, but in my experience, an informed patient who is involved in the decision infrequently requests operative treatment to reconstruct or to salvage the arthritic joint.

Distal Interphalangeal Joint

Infected mucous cysts are typically effectively treated with oral antibiotics (cephalexin or the equivalent to treat *Staphylococcus aureus* infection). Operative treatment is necessary only for long-standing cases with potential osteomyelitis. Because the joint is already severely damaged, there is no need to be concerned about joint damage from the infection.

Aspiration of mucous cysts is not expected to be curative. Patients sometimes elect aspiration to reduce the size of a very large cyst or to improve skin cover when it has become thin and translucent. The recurrence rate is also high after surgery. Patients must choose between leaving the cyst alone and making an attempt to resolve it with surgery, being mindful of the discomfort, inconvenience, and risks of surgery as well as the high recurrence rate.

Patients usually request arthrodesis when there is substantial ulnar or radial deviation of the distal interphalangeal joint. It is more aesthetic than functional. Patients rarely request distal interphalangeal joint arthrodesis for pain or disability.

Proximal Interphalangeal Joint

It is uncommon to operate on idiopathic osteoarthritis of the proximal interphalangeal joint, probably a reflection of the relatively low incidence and severity of osteoarthritis at this joint compared with the distal interphalangeal joint and effective coping with an insidious, slowly progressive disease. Arthrodesis and arthroplasty are both options at this joint and the indication is usually pain relief.

Arthrodesis is more predictable. Arthroplasty is used only in patients who are motivated to retain some mobility at the sacrifice of pain relief and stability [11]. Newer arthroplasties made of pyrolytic carbon (PyroCarbon) or metal have not proved superior to conventional Silastic rubber arthroplasty [12].

Trapeziometacarpal Joint

The trapeziometacarpal joint is the most common upper extremity site of surgical reconstruction for osteoarthritis. Operative treatment consists of the salvage procedures

arthrodesis and resection arthroplasty [13,14]. Arthrodesis is less used because of the need for protection, the risk of nonunion, and the inability to place the hand flat on the table that is often bothersome to patients. Some surgeons favor arthrodesis in younger patients who use the hand for strength, but this recommendation is not evidence based.

Reconstruction of the palmar oblique ligament without resection of the trapezium and extension osteotomy of the metacarpal are controversial treatments for a painful trapeziometacarpal joint in a relatively young patient with limited radiographic signs of arthritis. Neither procedure is known to affect the natural history of the disease, and until it is demonstrated to be better than sham surgery, it should be considered to be strongly subject to the placebo or meaning effect, in my opinion [13]. Patients with laxity related to a connective tissue disorder are not helped by ligament reconstruction; their only option is arthrodesis, and it is elective.

There are many variations of resection arthroplasty [7,14,15]. The sources of variation include the following: the amount of trapezium resected; whether the palmar oblique ligament is reconstructed and what technique and tendon are used; what, if anything, is placed in the space created by trapeziectomy (rolled up tendon, prosthesis, or other commercial spacers); operative approach (volar, direct radial, arthroscopic); pinning of the joint; and tendons used or included in the reconstruction. Simple trapeziectomy has been shown to be as effective as more sophisticated techniques in some prospective randomized trials [16], but many hand surgeons find this simple resection arthroplasty relatively unappealing. I favor simple trapeziectomy for its simplicity, safety, and quicker recovery [16].

Potential Disease Complications

Hand osteoarthritis is a chronic, progressive disease that is a nuisance and not a danger. The only potential complications are associated with treatments.

Potential Treatment Complications

Nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. The newer nonsteroidal anti-inflammatory drugs (e.g., cyclooxygenase 2 inhibitors) have been associated with cardiovascular risks [17].

The primary risks associated with injections are infection and an allergic reaction to the medication used, but both are extremely rare. Some patients develop a hematoma or complain of substantial pain after an injection.

Potential surgical complications include wound infection, neuroma, and hematoma. The major source of dissatisfaction after surgery is persistent pain, and its sources are controversial.

714.0 Rheumatoid arthritis

ICD-10 Code

M06.9 Rheumatoid arthritis, unspecified

Definition

Rheumatoid arthritis is a systemic inflammatory disorder of unknown etiology. It is a progressive condition that results in deformity and dysfunction when synovial inflammation erodes cartilage, bone, and soft tissues. However, the widespread early use of methotrexate has transformed rheumatoid arthritis into a much less devastating disease [1]. The availability of targeted biologic therapies, such as the tumor necrosis factor (TNF) antagonists, has further improved the outcome of rheumatoid arthritis [2]. Surgery has become much less common and more straightforward in patients with rheumatoid arthritis. For a detailed discussion of rheumatoid arthritis, see Chapter 151.

Symptoms

Presenting symptoms in the hand include joint pain in the fingers as well as stiffness and swelling, typically involving the proximal interphalangeal and metacarpophalangeal joints but—in contrast to osteoarthritis—sparing the distal interphalangeal joints. Stiffness usually is most pronounced in the morning. If it is left untreated, rheumatoid arthritis may result in progressive deformity and disability.

Physical Examination

The evaluation of a rheumatoid arthritic hand should include the following: joint pain and inflammation; joint stability; limitations in active and passive range of motion for grip and pinch strength deficits; limitations in hand dexterity; and degree of disability with respect to self-care, vocational activities, and recreational activities.

Early in the course of disease, involved joints are usually stiff, painful, and swollen as synovitis predominates. In some patients, the first sign of rheumatoid arthritis may be extensor tenosynovitis on the dorsum of the hand and wrist (although this can also be an idiopathic condition). Chronic synovitis may destroy capsuloligamentous and tendinous structures, creating laxity and deformity. In rheumatoid arthritis, in contrast to the arthritis of systemic lupus erythematosus, this soft tissue damage is usually accompanied by destruction of bone with periarticular erosions evident on radiographs.

Typical hand deformities associated with advanced rheumatoid arthritis include boutonnière deformity (flexion deformity of the proximal interphalangeal joint and extension deformity of the distal interphalangeal joint) and swan-neck deformity (hyperextension of the proximal interphalangeal joint with flexion of the distal interphalangeal joint). It is not uncommon to see varying patterns on the fingers of one hand (Fig. 34.1).

Inability to extend the index through small fingers may be due to the following: deformity and subluxation or dislocation of the index through small finger metacarpophalangeal joints; ulnar translocation of the extensor tendons due to laxity and destruction of the radial sagittal bands; extensor tendon ruptures due to a combination of dorsal tenosynovitis and distal radioulnar joint deformity or abrasions; or posterior interosseous nerve compression by elbow synovitis. Ulnar drift of the fingers usually accompanies each of these deformities.

Rupture of the extensor tendons usually proceeds in a sequence from ulnar to radial, referred to as the Vaughn-Jackson syndrome [3]. Mannerfelt syndrome is the equivalent on the volar side, progressing from the thumb to the index and long fingers, producing tendon ruptures as a result of synovitis and scaphotrapezial trapezoid irregularity [4].

Synovitis in the wrist results in volar and ulnarward subluxation and supination of the hand in relation to the

FIGURE 34.1 Rheumatoid hand. Note the multiple presentations in one hand: ulnar drift at the metacarpophalangeal joints, swan-neck deformities of the third and fourth fingers, boutonnière deformity of the fifth finger, volar subluxation at the metacarpophalangeal joint, and radial rotation of the metacarpals.

forearm. This wrist deformity can exacerbate the Vaughn-Jackson syndrome and ulnar drift.

Extensive synovitis or tenosynovitis can cause nerve compression, but, except for carpal tunnel syndrome, this is uncommon now that synovitis is controlled by effective medications.

Functional Limitations

Surgery is considered when correction of a deformity will improve function. Rheumatoid deformities typically progress slowly, and patients often adapt well. In some cases, realignment or stabilization of one joint or finger will actually decrease function because it will interfere with an adaptive mechanism. For this reason, surgery for rheumatoid deformity must carefully match the functional desires and goals of the patient with the risks and benefits of operative intervention. Many severe deformities are left untreated when patients have adapted well.

Diagnostic Studies

The diagnosis of rheumatoid arthritis is based predominantly on its clinical presentation. Laboratory testing is used to monitor disease activity and toxicity of drug therapy. Acute phase reactants, such as C-reactive protein and erythrocyte sedimentation rate, may be elevated in the setting of active joint inflammation. Most patients with rheumatoid arthritis have circulating rheumatoid factor or anti-citrullinated protein antibodies. The presence of one of these serologic markers suggests a more aggressive and destructive disease course.

Diffuse periarticular osteopenia is the earliest radiographic sign of rheumatoid arthritis. Joint space narrowing and periarticular erosions may be observed in more than half of patients with rheumatoid arthritis during the first 2 years of disease [5]. If left untreated, joints involved by rheumatoid arthritis may be destroyed by chronic synovitis.

Diagnostic ultrasonography is often used to detect early erosions and joint swelling in patients with rheumatoid arthritis [6]. Magnetic resonance imaging of the hand may reveal synovitis and erosions early in the course of rheumatoid

arthritis. However, radiographs remain the reference standard for diagnostic imaging of rheumatoid arthritis.

Differential Diagnosis

- Septic arthritis
- Psoriatic arthritis
- Systemic lupus erythematosus
- Gout
- Lyme disease
- Calcium pyrophosphate dihydrate deposition disease (pseudogout)

Treatment

Initial

Nonsteroidal anti-inflammatory drugs decrease pain and inflammation by inhibiting prostaglandin synthesis; they do not inhibit synovial proliferation and thus do not slow the progression of bone erosion and joint destruction. Low-dose corticosteroids also reduce symptoms of joint inflammation; but unlike nonsteroidal anti-inflammatory drugs, low-dose corticosteroids retard the progression of joint destruction. However, the widespread use of corticosteroids is limited by their many deleterious side effects, including osteoporosis, osteonecrosis of bone, cataracts, cushingoid features, and hyperglycemia.

Since the mid-1980s, the widespread and early use of low-dose weekly methotrexate has transformed rheumatoid arthritis into a much less destructive disease than it had been previously. Leflunomide also may be used to suppress synovial proliferation and joint destruction [7]. Other disease-modifying antirheumatic drugs (DMARDs) that have been used to treat rheumatoid arthritis include antimalarial drugs such as hydroxychloroquine, sulfasalazine, intramuscular and oral gold, D-penicillamine, immunosuppressive agents (azathioprine and cyclophosphamide), and cyclosporine.

Since the late 1990s, targeted biologic therapies have been used to treat rheumatoid arthritis and other inflammatory diseases. TNF antagonists, such as adalimumab, certolizumab pegol, etanercept, golimumab, and infliximab result in the rapid and marked improvement of signs and symptoms of joint inflammation and dramatically slow the rate of joint destruction [8–12]. Abatacept (an inhibitor of T-cell costimulation), tocilizumab (a monoclonal anti-IL-6 receptor antibody), and rituximab (a monoclonal anti-B-cell antibody) have also been approved by the U.S. Food and Drug Administration to treat patients with rheumatoid arthritis; tocilizumab and rituximab are each approved to treat patients who have had an inadequate response to one or more TNF antagonists, whereas abatacept is approved to treat patients who have had an inadequate response to one or more DMARDs, such as methotrexate or TNF antagonists. TNF antagonists, abatacept, and rituximab are each effective when used in combination with methotrexate [9,13–15]. Tofacitinib (an oral Janus kinase 3 [JAK3] inhibitor), has recently been approved by the U.S. Food and Drug Administration, either as monotherapy or in combination with methotrexate or other nonbiologic DMARDs, to treat patients with rheumatoid arthritis who have had an inadequate response or intolerance to methotrexate [16].

Rehabilitation

Rehabilitation of the rheumatoid hand involves adaptation and work simplification instructions (refer to Table 33.1), splinting regimens, heat modalities, active range of motion exercise, and resistive exercise (see also Chapter 33).

Flexor and Extensor Tendon Reconstruction Postoperative Rehabilitation

The rehabilitation protocol after flexor and extensor tendon reconstruction varies according to the injury, operative technique, and preferences of the surgeon. Most surgeons protect repairs with cast or splint immobilization for 4 to 6 weeks. Active and active-assisted motion is then encouraged.

Metacarpophalangeal Joint Postoperative Rehabilitation

There is also substantial variation in the preferences of surgeons for rehabilitation after metacarpophalangeal arthroplasty. However, continuous passive motion and dynamic splinting have not proved better than a month of cast immobilization with active-assisted motion exercises thereafter [17].

Interphalangeal Joint Postoperative Rehabilitation

Interphalangeal joint arthrodesis is usually performed with internal fixation that allows the patient to be splint free and to work on active motion of the metacarpophalangeal joints immediately. Rehabilitation after implant arthroplasty of the proximal interphalangeal joint varies according to operative exposure. Patients treated through a volar exposure begin active exercises within a few days, but patients in whom the extensor tendon or a collateral ligament was taken down and repaired during surgery are immobilized for about 4 weeks initially.

Procedures

Injection of intra-articular steroids may reduce the activity of the synovitis in a given joint. A good rule of thumb is no more than three injections spaced at least 3 months apart (refer to Chapter 33 for procedure details).

Surgery

Indications for surgery include pain relief and functional restoration. Another benefit—and the source of patients' satisfaction—of hand surgery in rheumatoid arthritis is improvement in the appearance of the hand [18]. The goals may be different when both hands have severe deformities. One may be addressed in a way that enhances fine motor skills, whereas the other is prepared for gross functional tasks requiring strength.

Some have advocated advancement from proximal to distal in rheumatoid hand reconstruction, arguing that if the hand cannot be placed in useful positions in space, postoperative rehabilitation will be hindered. Wrist deformity affects hand deformity and is usually corrected first or simultaneously [19].

Extensor Tendon Surgery

Patients with extensor tenosynovitis present with a painless dorsal wrist mass distal to the retinaculum of the wrist. Tenosynovectomy is indicated to establish diagnosis and to

prevent tendon rupture, which is uncommon after this surgery. Treatment of tendon rupture involves transfer of the distal end of the ruptured tendon to an adjacent tendon. In the event of multiple tendon ruptures, tendon transfer of the extensor indicis proprius or the flexor digitorum superficialis of the long or ring finger may be indicated. When both wrist extensor tendons are ruptured on the radial side, arthrodesis is preferred [20].

Flexor Tendon Surgery

Flexor tenosynovitis can contribute to pain, morning stiffness, volar swelling, and median nerve compression. A tenosynovitis may be diffuse or create discrete nodules that can limit tendon excursion. At the wrist, tenosynovectomy and biopsy are indicated for median nerve compression, painful tenosynovial mass, or tendon rupture. The tendon most commonly ruptured is the flexor pollicis longus. A tendon bridge graft can be used if the rupture is relatively recent, but tendon transfer or arthrodesis of the interphalangeal joint is more commonplace. A ruptured flexor digitorum profundus tendon is sutured to an adjacent intact profundus tendon to another finger. The presence of one tendon rupture is an indication to promptly perform surgery to prevent further tendon damage.

The palm is the most common location of flexor tenosynovitis. Indications for flexor tenosynovectomy in the palm include pain with use, triggering, tendon rupture, and passive flexion of the fingers that is greater than active flexion.

Metacarpophalangeal Joint Surgery

The most common deformities of the metacarpophalangeal joint are palmar dislocation of the proximal phalanx and ulnar deviation of the fingers. As the inflammatory process disrupts the digit stabilizers, anatomic forces during use of the hand propel the digits into ulnar deviation. Metacarpophalangeal synovectomy is rarely performed in patients with rheumatoid arthritis. Silicone implant arthroplasty is indicated in patients with diminished range of motion, marked flexion contractures, and severe ulnar drift. Arthroplasty does not improve motion, it just places it in a more functional and aesthetic range. Deformities recur over time [21].

Interphalangeal Joint Surgery

There are two types of proximal interphalangeal joint deformities, the boutonnière deformity and the swan-neck deformity. Surgical intervention, such as flexor sublimis tenodesis or oblique retinacular ligament reconstruction, is designed to prevent hyperextension. On occasion, there is a mallet of the distal interphalangeal joint that can be corrected by partial extension. In later disease, intrinsic tightness requires release. In late swan-neck deformity with loss of proximal interphalangeal movement, implant arthroplasty of the proximal interphalangeal joint as well as sufficient soft tissue immobilization and release to achieve movement in flexion once again can help. In late deformities, especially in the index and middle fingers, arthrodesis may be preferred. Implant arthroplasties are recommended for the proximal interphalangeal joints of the ring and small fingers. No advantage has been demonstrated for newer implant designs (e.g., pyrolytic carbon [PyroCarbon]), which are not clearly better than traditional silicone arthroplasty [22].

For boutonnière deformity, extensor tenotomy over the middle phalanx (Fowler) can gain distal interphalangeal joint flexion. In late disease, fixed flexion contracture with inability to passively extend the proximal interphalangeal joint may be present. Treatment options are proximal interphalangeal arthrodesis and arthroplasty with a Silastic implant [23].

The thumb presents with two types of deformities. One is the boutonnière deformity with flexion of the metacarpophalangeal joint and extension of the interphalangeal joint. These are usually treated with metacarpophalangeal arthrodesis. The other is the swan-neck deformity with abduction subluxation of the base of the thumb metacarpal, hyperextension of the metacarpophalangeal joint, and flexion deformity of the interphalangeal joint of the thumb. For severe swan-neck deformity, carpometacarpal arthrodesis or arthroplasty may help.

Potential Disease Complications

Complications of rheumatoid disease in the hand include severe loss of function with complete joint destruction, severe flexion and ulnar deviation deformities of the digits, and severe swan-neck and boutonnière deformities.

Potential Treatment Complications

Complications of operative treatment include infection, hardware breakage, nonunion, Silastic implant breakage, silicone synovitis, and progression of deformity [24]. All of these eventually lead to loss of function of the hand.

Nonsteroidal anti-inflammatory drugs have associated toxicities that most commonly affect the gastric, hepatic, renal, and cardiovascular systems. Methotrexate may cause liver, hematologic, and, less frequently, lung toxicity. Thus, all patients receiving low-dose weekly methotrexate therapy should have complete blood count and liver function monitoring at least every 8 weeks [25].

The efficacy of targeted biologic therapies and of small molecule kinase inhibitors is tempered by potential toxicities. Because treatment with a TNF antagonist, tocilizumab, or tofacitinib each increases the risk for reactivation of latent tuberculosis, all patients for whom one of these medications is considered should undergo purified protein derivative (PPD) testing or an interferon- γ -release assay (IGRA). If the PPD test result is reactive or if the IGRA result is positive, treatment of latent tuberculosis should be initiated before treatment is begun with any of these drugs. Also, because the severity of bacterial infections may be increased in patients receiving treatment with rituximab, a TNF antagonist, tocilizumab, or tofacitinib, all patients taking these medications should be warned to seek immediate medical attention if signs or symptoms of infection develop [2].

M19.232 Secondary osteoarthritis, left wrist
M19.239 Secondary osteoarthritis, unspecified wrist
M93.1 Kienböck's disease of adults

Definition

Kienböck disease is avascular necrosis of the lunate, unrelated to acute fracture, often leading to fragmentation and collapse. Although the precise etiology and natural history of this disorder remain unknown, interruption of the blood supply to the lunate is undoubtedly a part of the process. Trauma has been implicated as a cause [1–3]. This disease occurs most often in the dominant hand of men in the age group of 20 to 40 years. Many of these patients are manual laborers who report a history of a major or repetitive minor injury. Associations have also been made between Kienböck disease and corticosteroid use, cerebral palsy, systemic lupus erythematosus, sickle cell disease, gout, and streptococcal infection.

An important radiographic observation has been made regarding the radius-ulna relationship at the wrist and the development of Kienböck disease [4]. In these patients, the ulna is generally shorter than the radius, a finding termed ulnar negative (or minus) variance. Normally, the lunate rests on both the radius and the triangular fibrocartilage complex

covering the ulnar head. It has been speculated that when the ulna is significantly shorter than the radius, a shearing effect occurs in the lunate, which can make it more susceptible to injury.

Symptoms

Presenting symptoms include chronic wrist pain, decreased range of motion, and weakness [5]. The pain is usually deep within the wrist, although the patient often points to the dorsum of the wrist, and is aggravated by activity. Some patients complain of a pressure-like pain that may awaken them. A history of recent trauma is often provided; however, many patients report having had long-standing mild wrist pain preceding the recent injury. Symptoms may often be present for months or years before the patient seeks medical attention.

Physical Examination

Mild dorsal wrist swelling and tenderness in the mid-dorsal aspect of the wrist may be present. Wrist flexion and extension are limited. Forearm rotation is usually preserved. Grip strength is often considerably less on the affected side because of pain.

Neurologic and vascular examination findings are normal.

Functional Limitations

Functional limitations include difficulty with heavy lifting, gripping, and activities involving the extremes of wrist motion. Many heavy laborers are unable to perform the essential tasks required of their occupation.

Diagnostic Studies

The initial diagnostic imaging for suspected Kienböck disease includes standard wrist radiographs. Early in the disease process, the radiographs may be normal. With time, a characteristic pattern of deterioration occurs, beginning with sclerosis of the lunate, followed by fragmentation, collapse, and finally arthritis [6,7] (Fig. 35.1). A radiographic staging system for Kienböck disease, proposed by Lichtman, is helpful in describing the extent of the disease and guiding treatment [1] (Table 35.1).

For clinical suspicion of Kienböck disease with normal radiographs, a technetium bone scan or magnetic resonance

FIGURE 35.1 Advanced Kienböck disease. Cystic and sclerotic changes are present within the collapsed lunate (arrow).

FIGURE 35.2 MRI in Kienböck disease. T1-weighted images demonstrate diffuse low signal within the lunate (arrow).

FIGURE 35.3 Posteroanterior view of the wrist demonstrating the proximal and distal carpal rows. a, scaphoid; b, lunate; c, triquetrum; d, pisiform; e, trapezium; f, trapezoid; g, capitate; and h, hamate. (From Jebson PJL, Kasdan ML, eds. *Hand Secrets*. Philadelphia, Hanley & Belfus, 1998:220.)

Table 35.1 Stages of Kienböck Disease

Stage I	Normal radiographs or linear fracture
Stage II	Lunate sclerosis, one or more fracture lines with possible early collapse on the radial border
Stage III	Lunate collapse
IIIA	Normal carpal alignment and height
IIIB	Fixed scaphoid rotation (ring sign), carpal height decreased, capitate migrates proximally
Stage IV	Severe lunate collapse with intra-articular degenerative changes at the midcarpal joint, radiocarpal joint, or both

imaging (MRI) may be helpful. In fact, MRI has supplanted plain radiography for the detection and evaluation of the early stages of Kienböck disease when there has been no trabecular bone destruction. Characteristic signal changes include decreased signal on T1-weighted and increased signal on T2-weighted images (Fig. 35.2). Computed tomography is more effective than MRI in assessing for fracture of the lunate, but it provides limited information about its vascularity (Figs. 35.3 and 35.4).

Differential Diagnosis

Wrist sprain
 Scapholunate ligament tear
 Osteoarthritis
 Ganglion
 Inflammatory arthritis (e.g., rheumatoid arthritis)
 Preiser disease (avascular necrosis of the scaphoid)
 Tendinitis
 Scaphoid fracture

Treatment

Initial

Given the limited information about the etiology and natural history of this uncommon disease, it is not surprising that the treatment has not been standardized. Without surgery, progressive radiographic collapse and radiographic arthritis almost invariably occur [5]. However, symptoms correlate only weakly with the radiographic appearance, and many patients maintain good long-term function even without

FIGURE 35.4 The stages of Kienböck disease. **A**, Stage I. T1-weighted MRI shows marked signal reduction in the lunate, compatible with loss of blood supply. **B**, Stage II. Density changes in the lunate as indicated by sclerosis. Note the ulnar minus variance. **C**, Stage IIIA. Collapse of the lunate. There are no fixed carpal derangements. **D**, Stage IIIB. Decreased carpal height and proximal migration of the capitate. Note the scaphoid cortical ring sign (arrow). **E**, Stage IV. Generalized degenerative changes in the carpus. (From Weinzwieg J, ed. *Plastic Surgery Secrets*. Philadelphia, Hanley & Belfus, 1999:605-606.)

surgery [8]. The goals of surgery ideally would be to relieve the pain and to halt the progression of the disease. Surgical interventions appear to be relatively effective in achieving the first goal but have not as yet reliably altered the radiographic deterioration of the lunate. Consequently, treatment options range from simple splints to external fixation and from radial shortening to vascularized grafts to fusions. Factors taken into consideration in assigning treatment include stage of the disease; ulnar variance; and age, occupation, pain, and functional impairment of the patient [9]. An argument can be made to treat young, active patients with early-stage disease more aggressively in an effort to prevent progression; however, intra-articular procedures invariably result in some permanent loss of motion.

Many clinicians prefer to begin with symptomatic treatment. Depending on the situation, this may involve a splint and activity modification or a short arm cast. However, an appropriate length of immobilization has not been established. Some clinicians have attempted this treatment for as long as 1 year, but most clinicians prescribe a cast for 6 to 12 weeks. The immobilization probably helps the pain associated with synovitis and with wrist activity and motion; however, it does nothing to alter the vascularity of the bone or the shear stresses across the lunate. The patient should be informed that the radiographs will, in all likelihood, demonstrate worsening of the disease over time.

Pain can be treated with analgesics, including nonsteroidal anti-inflammatory drugs. Narcotic medications are generally not recommended because of the chronicity of this condition.

Rehabilitation

Rehabilitation does not play a major role early in conservative treatment. Once the pain has subsided, gentle range of motion and strengthening may be initiated. Therapy is important for the postoperative patient, particularly if an intra-articular procedure has been performed or an external fixator has been applied. The wrist is typically immobilized postoperatively until the vascularized graft or fusion has healed (about 6 weeks). At that point, occupational or physical therapy can effectively begin with gentle range of motion exercises, gradually progressing to strengthening exercises.

Procedures

Intra-articular steroids are of no proven benefit in the management of Kienböck disease.

Surgery

Some authors think that most patients treated nonoperatively do well [6], whereas others think that surgery is indicated for most patients with Kienböck disease [10–12]. The surgical treatment options for this disease may be divided into stress reduction (unloading), revascularization, lunate replacement, and salvage procedures [9]. Radial shortening of 2 to 3 mm is currently the most popular procedure for early-stage Kienböck disease in the setting of ulnar minus variant [10,13]. The goal is to make the radius and ulna lengths the same and thus to reduce shear forces on the

lunate. Other unloading procedures include limited wrist fusion, capitate shortening, and external fixation [14]. Revascularization procedures have shown promise in the management of avascular necrosis of the lunate [15,16]. The most popular of the pedicled bone grafts, based on the extensor compartmental arteries of the wrist, is transplanted from the distal radius into the lunate. In one series with relatively short-term follow-up, significant pain relief was observed in 92% of patients, and actual lunate revascularization was seen in 60% on follow-up MRI [15]. An intriguing method of indirect revascularization of the lunate has been proposed by Illarramendi and colleagues [17], who perform a metaphyseal drilling of the radius and ulna, without violating the wrist joint. In their series, 16 of 20 patients were pain free at an average of 10 years postoperatively. Silastic lunate replacement has been abandoned because of implant dislocation and synovitis.

When the lunate has collapsed to the point that it is not reconstructable, salvage procedures such as proximal row carpectomy and partial or total wrist arthrodesis are considered. Obviously, these procedures sacrifice motion in an effort to provide pain relief. The results of the various procedures are dependent, to some extent, on the stage of the disease. Wrist arthroscopy may be of some benefit in determining the extent of the disease and in selecting the appropriate salvage procedure [18]. Regardless of the specific type of salvage procedure, most authors report 70% to 100% satisfaction of patients. Advanced arthritis (stage IV) is generally best treated with a total wrist arthrodesis.

Potential Disease Complications

Without surgery, progressive radiographic collapse of the lunate and arthritis of the wrist invariably occur.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Infection is uncommon after hand surgery. Complications such as nerve injury, painful hardware, and stiffness of the wrist and digits are inherent in hand surgery. A radial shortening osteotomy or partial wrist fusion may fail to heal (nonunion). Secondary wrist arthritis can develop after partial wrist fusions or proximal row carpectomy. Grip strength virtually never returns to normal. Finally, and most important, whether surgery favorably alters the natural history of this rare condition remains unproven.

CHAPTER 36

Median Neuropathy (Carpal Tunnel Syndrome)

Meijuan Zhao, MD
David T. Burke, MD, MA

Synonyms

Median nerve entrapment at the wrist or carpal tunnel syndrome
Median nerve compression

ICD-9 Code

354.0 Carpal tunnel syndrome

ICD-10 Codes

G56.00 Carpal tunnel syndrome, unspecified upper limb
G56.01 Carpal tunnel syndrome, right upper limb
G56.02 Carpal tunnel syndrome, left upper limb

Definition

Carpal tunnel syndrome (CTS), an entrapment neuropathy of the median nerve at the wrist, is the most common compression neuropathy of the upper extremity. This syndrome produces paresthesias, numbness, pain, subjective swelling, and, in advanced cases, muscle atrophy and weakness of the areas innervated by the median nerve. The condition is often bilateral, although the dominant hand tends to be more severely affected.

CTS is thought to result from a compression of the median nerve as it passes through the carpal tunnel. The clinical presentation is variable. Whereas there is some variation as to what should be included in this definition, CTS is most often thought to involve sensory changes in the radial 3½ digits of the hand with burning, tingling, numbness, and a

subjective sense of swelling. Those affected often first note symptoms at night. In the later stages, complaints include motor weakness in the thenar eminence.

It is helpful to think of the carpal tunnel as a structure with four sides, three of which are defined by the carpal bones and the fourth, the “top” of the tunnel, by the transverse carpal ligament (Figs. 36.1 and 36.2). Passing through the tunnel are the median nerve and nine tendons with their synovial sheaths; these include the flexor pollicis longus, the four flexor digitorum superficialis, and the four flexor digitorum profundus tendons. None of the sides of the tunnel yields well to expansion of the fluid or structures within. Because of this, swelling will increase pressure within the tunnel and may result in compression of the median nerve. CTS occurs more commonly in women than in men, with a prevalence in the general adult population ranging from 2.7% to 5.8% [1,2]. It is most common in middle-aged persons between the ages of 30 and 60 years. The older adults may have objective clinical and electrophysiologic evidence of a more severe median nerve entrapment [3]. Most cases of CTS are idiopathic with congenital predisposition. Some focal or systemic conditions, such as wrist injury, arthritis, diabetes, thyroid disease, rheumatoid arthritis, and pregnancy, can increase pressure on the median nerve in the carpal tunnel and contribute to the development of CTS. Prolonged postures in extremes of wrist flexion or extension, repetitive use of the flexor muscles, and exposure to vibration are the primary exposures that have been reported [4–7]. The pathophysiologic mechanism of CTS involves a combination of mechanical trauma, increased pressure, and ischemic injury to the median nerve within the carpal tunnel [8].

Symptoms

The classic symptoms of CTS include numbness and paresthesias in the radial 3½ fingers (Fig. 36.3). A typical early complaint is awakening in the night with numbness or pain in the fingers. Symptoms during the day are often brought out by activities placing the wrist in substantial flexion or extension or requiring repetitive motion of the structures that traverse the carpal tunnel. Many patients report symptoms outside the distribution of the median nerve as well [9].

FIGURE 36.1 Radiographic demonstration of the carpal tunnel (for orientation, the hand is in the same position in the radiograph). The carpal tunnel is formed radially, ulnarly, and dorsally by the carpal bones. (From Concannon M. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

FIGURE 36.2 The volar carpal ligament (*line*) forms the roof of the carpal tunnel. This thick, fibrous structure does not yield to expansion, and increased pressure within the carpal tunnel can cause impingement of the median nerve. (From Concannon M. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

Numbness and pain in the hand may also be accompanied by volar wrist pain and aching at the forearm. The patient may describe the symptoms as being positional, with symptoms relieved by the shaking of a hand, often referred to as the flick sign [10].

FIGURE 36.3 Patients with carpal tunnel syndrome complain of numbness or paresthesia within the median nerve distribution (orange area, arrows). (From Concannon M. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

Patients may complain of a sense of swelling in the hands, often noting that they have difficulty wearing jewelry or watches, with this sensation fluctuating throughout the day or week. Some patients also report dry skin and cold hands. In the later stages of CTS, the numbness may become constant and motor disturbances more apparent, with complaints of weakness manifested by a functional decrease of strength. Patients may then report dropping objects.

Physical Examination

A two-point sensory discrimination test is thought to be the most sensitive of the bedside examination techniques. This involves a comparison of the two-point discriminating sensory ability of the median with that of the ulnar nerve distribution of the hand. Careful observation of the hands, comparing the affected side with the unaffected side and comparing the thenar and hypothenar eminences of the same hand, may reveal an increasing asymmetry. Weakness of the thenar intrinsic muscles of the hand can be tested with a dynamometer or clinically by testing abduction of the thumb against resistance. The more common special tests include the Phalen, the Tinel, and the nerve compression tests. The Phalen test involves a forced flexion at the wrist to 90 degrees for a period of 1 minute; a positive test result

FIGURE 36.4 Phalen test. Patients maximally flex both wrists and hold the position for 1 to 2 minutes. If symptoms of numbness or paresthesia within the median nerve distribution are reproduced, the test result is positive. (From Concannon M. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

reproduces the symptoms of CTS (Fig. 36.4). The reverse Phalen maneuver is the same test completed with forced extension. The Tinel test involves tapping sharply over the volar aspect of the wrist just distal to the distal wrist crease. The test result is positive when a sensory disturbance radiates down the region of the distribution of the median nerve. The nerve compression test involves the placement of two thumbs over the roof of the carpal tunnel, with pressure maintained for 1 minute. The test result is positive if symptoms are reproduced in the area of the distribution of the median nerve. A review showed an overall estimate of 68% sensitivity and 73% specificity for the Phalen test, 50% sensitivity and 77% specificity for the Tinel test, and 64% sensitivity and 83% specificity for the carpal compression test [11]. Two-point discrimination and testing of atrophy or strength of the abductor pollicis brevis proved to be specific but not very sensitive. [11].

Functional Limitations

Functional limitations of CTS often include difficulty with sleep due to frequent awakenings by the symptoms. Because certain sustained or repetitive motions are difficult, tasks that often become more difficult include driving a car and sustained computer keyboard or mouse use at work. The later symptom of weakness in the thenar eminence may result in difficulty maintaining grip. Profound CTS may result in functional limitations, such as the inability to tie one's shoes, to button shirts, and to put a key in a lock.

Diagnostic Studies

Whereas CTS is a syndrome rather than a singular finding, it is often suggested that the "gold standard" test of CTS is electrodiagnostic testing. Electromyography and nerve conduction studies can confirm the diagnosis, determine the severity (if any) of nerve damage, guide and measure the effect of treatment, and rule out other conditions such as

radiculopathy and brachial plexopathy. Ultrasound studies, which reveal an enlarged median nerve, may assist with the diagnosis [12]. Typically, the ultrasound examination may show flattening of the nerve within the tunnel and enlargement of the nerve proximal and distal to the tunnel. Pooling of recent articles seems to confirm that sonography using cross-sectional area of the median nerve could not be an alternative to electrodiagnostic testing for diagnosis of CTS but could give complementary results. Ultrasound examination should be considered in doubtful cases or secondary cases of CTS [13].

Others have advocated the injection of corticosteroids or bupivacaine into the carpal tunnel. If the injection is accompanied by a relief of symptoms, it provides diagnostic evidence of CTS [14].

A wrist radiograph may be helpful if a fracture or degenerative joint disease is suspected.

Blood tests should be ordered if underlying rheumatologic disease or endocrine disturbance is suspected. These include fasting blood glucose concentration, erythrocyte sedimentation rate, thyroid function, and rheumatoid factor.

Differential Diagnosis

- Cervical radiculopathy in C5 to T1 distribution
- Brachial plexopathy
- Proximal median neuropathy
- Ulnar or radial neuropathy
- Generalized neuropathy
- Arthritis of carpometacarpal joint of thumb
- de Quervain tenosynovitis
- Tendinitis of the flexor carpi radialis
- Raynaud phenomenon
- Hand-arm vibration syndrome
- Arthritis of the wrist
- Gout

Treatment

Initial

Once the diagnosis is established, treatment should begin with conservative management in patients with mild disease. Nighttime wrist splinting (Fig. 36.5) in a neutral

FIGURE 36.5 Wrist splint in neutral position.

position may help reduce or completely relieve CTS symptoms. Wrist splinting in neutral position may be more effective than in 20-degree extension in the short term [15]. Full-time use, if tolerable, has been shown to provide greater improvement of symptoms and electrophysiologic measures than night-only use [16]. Compliance with full-time use is more difficult [16]. Most patients will achieve maximal symptom relief through splinting within 2 to 3 weeks. If current treatment fails to resolve symptoms within 2 to 7 weeks, another nonsurgical treatment or surgery is suggested [17]. Nonsteroidal anti-inflammatory drugs are frequently prescribed as an adjunct to wrist splinting. However, studies have demonstrated that nonsteroidal anti-inflammatory drugs, vitamin B₆, and diuretics are often no more effective than placebo in relieving the symptoms of CTS [15].

The use of oral steroids (prednisone in doses of 20 mg daily for the first week and 10 mg daily for the second week [18], or prednisolone at 25 mg daily for 10 days [19]) has proved to be of some benefit, although not as impressive as the results noted through injection (see later) [19]. However, the effectiveness of oral or injected steroids was not maintained in the long term [15].

Underlying conditions, such as hypothyroidism, rheumatoid arthritis, or diabetes, should be treated. Frequent periods of rest of the wrist should be prescribed, especially when vocational activities involve sustained positioning or repetitive and forceful flexion or extension of the wrist. Ice after periods of use may be effective for symptom relief. Positioning of the body while a task is being performed should be reviewed to relieve unnecessary strain as necessary motions are performed.

Rehabilitation

Rehabilitation must address the patterns of hand use, which exacerbates the symptoms of CTS in many individuals. Lifestyle modifications, including decreasing repetitive activity and using ergonomic devices, have been traditionally advocated but have inconsistent evidence to support their effectiveness. Occupational therapists can be helpful in instructing flexion and extension stretching of the wrist and forearm. Although many therapists advocate strengthening as part of a treatment program, aggressive strengthening exercises should be avoided until symptom relief is nearly complete.

Icing after long periods of use has been advocated to reduce the pain and swelling. In addition, it is important that patients be instructed in a program of general physical conditioning; generalized deconditioning exacerbates the symptoms of CTS [20].

There is no evidence for the effectiveness of postoperative splinting [15]. It is suggested that the wrist not be immobilized postoperatively after routine carpal tunnel surgery [17]. Active motion of the hand and wrist should start immediately postoperatively to prevent joint stiffness and to ensure adequate glide of the tendons and median nerve in the carpal tunnel. Passive range of motion should be initiated at least 4 weeks postoperatively for mobilization of stiff joints and tendons. Strengthening is initiated at 3 to 4 weeks as wounds heal and inflammation resolves [21].

On average, postsurgical patients were able to return to driving in 9 days, to activities of daily living in 13 days, and to work in 17 days [22].

Procedures

The patient can also be treated with corticosteroid injections into the carpal tunnel. A number of authors have suggested various injection techniques to avoid direct injury to the median nerve [23–26].

For injection into the carpal tunnel (Fig. 36.6), 1 mL of steroid (triamcinolone, 40 mg/mL) can be injected under sterile conditions. For delivery, one should use a $\frac{5}{8}$ -inch, 27-gauge needle, placing the needle proximal to the distal wrist crease and ulnar to the palmaris longus tendon. The needle should be directed dorsally and angled at 30 degrees to a depth of about $\frac{5}{8}$ inch (the length of the needle) or contact with a flexor tendon. Slowly inject 1 mL of the corticosteroid. Anesthetics are not typically used in this injection unless for diagnostic verification. In individuals lacking a palmaris longus tendon (about 2% to 20% of the population), the needle can be placed midpoint between the ulna and radial styloid process. The injection will increase the volume of fluid within the carpal tunnel and thus may exacerbate the discomfort for a few hours; relief is expected within the 24 to 48 hours after injection. Although effectiveness is primarily short term, corticosteroid injection may be particularly useful to control the pain and to reduce symptoms for patients wishing to delay surgical treatment.

It has been reported that ultrasound-guided carpal tunnel injection improves the performance, clinical outcomes, and cost-effectiveness of injection of the carpal tunnel compared with conventional blind, palpation-guided injection

FIGURE 36.6 Preferred method for ulna bursa injection. Needle puncture is just ulnar to the palmaris longus tendon. The circle is over the pisiform bone. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

in a single randomized controlled trial [27]. However, the exact role of ultrasound guidance for carpal tunnel injection is still arguable [28].

Surgery

Carpal tunnel release surgery should be considered in patients with symptoms that do not respond to conservative measures and for whom electrodiagnostic testing clearly confirms median neuropathy at the wrist. Surgery or another nonsurgical treatment is suggested when the current treatment fails to resolve symptoms within 2 to 7 weeks [17]. Six weeks to 3 months of conservative treatment is reasonable in patients with mild disease [29].

Early surgery is indicated when there are signs of atrophy or muscle weakness. The optimal timing of surgery in the natural history of CTS has not been established, although timing is an important factor for total recovery after surgery. A long-lasting compression could result in irreversible axonal damage, which would not improve despite surgical intervention [15]. Surgical treatment has been shown to lead to better outcome than nonsurgical treatment [30]. The primary reason for a poor result is an error in diagnosis.

The open release of the transverse carpal ligament represents the standard procedure and can be performed by dividing the transverse carpal ligament through a small open wrist incision. The reliability of and good visualization provided by the open technique continue to make it the preferred operation for many hand surgeons [31]. The endoscopic techniques were introduced in the late 1980s to be minimally invasive and to prevent the palmar scarring. Both methods have equal efficacy and provide excellent outcomes in relieving symptoms of CTS [32], with satisfaction rates up to 90%. Potential benefits of the endoscopic technique, including a more rapid functional recovery, must be weighed against the technique's increased cost and higher complication rate [32].

Potential Disease Complications

As with any insult to a peripheral nerve, untreated CTS may result in chronic sensory disturbance or motor impairment in the area serviced by the median nerve. It is important that the clinician be wary of this and not allow the nerve disturbance to progress to permanent nerve damage.

Potential Treatment Complications

Although oral analgesics may be important for symptomatic relief early in the stages of CTS, gastric, renal, and hepatic complications of nonsteroidal anti-inflammatory drugs should be monitored. Complications from local corticosteroid injections include infection, bleeding, skin depigmentation, skin and fat atrophy, potential for tendon rupture, and potential for injury to the median nerve at the time of injection.

Surgical complications have been noted to be few in the literature. These include accidental transection of the median nerve, with permanent loss of function distal to the transection. In addition, some have suggested that endoscopic surgery might damage the Berrettini branch of the median nerve, a sensory branch [33]. Whereas complications of

surgical intervention are thought to be relatively infrequent, a number have been reported. The most common complication of surgical intervention is the incomplete sectioning of the transverse carpal ligament. Other potential complications include injury to the median nerve, palmar cutaneous branch, recurrent motor branch, and superficial palmar arch; hypertrophied or thickened scar due to inappropriate incision; tendon adhesions because of wound hematoma; recurrence because of repair of the ligament; bowstringing of flexor tendons; malposition of the median nerve; inappropriate separation of the nerve fibers from surrounding scars; pillar pain; and reflex sympathetic dystrophy.

CHAPTER 37

Trigger Finger

Keith A. Bengtson, MD

Julie K. Silver, MD

Synonyms

Stenosing tenosynovitis
Digital flexor tenosynovitis
Locked finger

ICD-9 Code

727.03 Trigger finger

ICD-10 Code

M65.30 Trigger finger, unspecified finger

Definition

Trigger finger is the snapping, triggering, or locking of a finger as it is flexed and extended. This is due to hypertrophy and fibrocartilaginous metaplasia at the tendon-pulley interface that does not allow the tendon to glide normally back and forth under the pulley. Trigger finger is thought to arise from high pressures at the proximal edge of the A1 pulley when there is a discrepancy in the diameter of the flexor tendon and its sheath at the level of the metacarpal head [1] (Fig. 37.1). The thumb (33%) and the ring finger (27%) are most commonly affected in adults, but 90% of pediatric trigger fingers involve the thumbs, 25% of which are bilateral [1]. It is often encountered in patients with diabetes and rheumatoid arthritis [2,3]. The relationship of trigger finger to repetitive trauma has been cited frequently in the literature [3–5]; however, the exact mechanism of this correlation is still open to debate [6]. Rarely, it is due to acute trauma or space-occupying lesions [7–9].

Symptoms

Patients typically complain of pain in the proximal interphalangeal joint of the finger, rather than in the true anatomic location of the problem—at the metacarpophalangeal joint. Some individuals may report swelling or stiffness in the fingers, particularly in the morning. Patients may also

have intermittent locking in flexion of the digit, which is overcome with forceful voluntary effort or passive assistance. Involvement of multiple fingers can be seen in patients with rheumatoid arthritis or diabetes [2,3]. In one study, the perioperative symptoms differed for trigger thumbs versus trigger fingers [10]. In this study, patients complained of pain with motion with trigger thumb; with trigger finger, they complained primarily of triggering and loss of range of motion.

Physical Examination

The essential element in the physical examination is the localization of the disorder at the level of the metacarpophalangeal joint. There is palpable tenderness and sometimes a tender nodule or crepitus over the volar aspect of the metacarpal head. Swelling of the finger may also be noted. Opening and closing of the hand actively produces a painful clicking as the inflamed tendon passes through a constricted sheath. With chronic triggering, the patient may have interphalangeal joint flexion contractures [11]. Therefore it is important to determine whether there is normal passive range of motion in the metacarpophalangeal and interphalangeal joints. Neurologic examination findings, including muscle strength, sensation, and reflexes, should be normal, with the exception of severe cases associated with disuse weakness or atrophy. Comorbidities can affect the neurologic examination findings as well (e.g., patients with diabetic neuropathy or carpal tunnel syndrome may have impaired sensation).

Functional Limitations

Functional limitations include difficulty with grasping and fine manipulation of objects due to pain, locking, or both. Fine motor problems may include difficulty with inserting a key into a lock, typing, or buttoning a shirt. Gross motor skills may include limitation in gripping a steering wheel or in grasping tools at home or at work.

Diagnostic Studies

This is a clinical diagnosis. Patients without a history of injury or inflammatory arthritis do not need routine radiographs [12]. Magnetic resonance imaging can confirm tenosynovitis of the flexor sheath, but this offers minimal advantage over clinical diagnosis [13]. Alternatively, a diagnostic ultrasound examination can show tendon nodules, tenosynovitis, and active triggering at the level of the A1 pulley.

FIGURE 37.1 The flexor tendon nodule catches under the annular ligament and produces the snapping or triggering sensation.

Differential Diagnosis

Dupuytren disease
Ganglion of the tendon sheath (retinacular cyst)
Tumor of the tendon sheath (giant cell tumor or space-occupying lesion, such as an amyloidosis)
Rheumatoid arthritis

Treatment

Initial

The goal of treatment is to restore the normal gliding of the tendon through the pulley system. This can often be achieved with conservative treatment. Typically, the first line of treatment is a local steroid injection [14]. The determination of whether to inject first or to try noninvasive measures is often based on the severity of the patient's symptoms (more severe symptoms generally respond better to injections), the level of activity of the patient (e.g., someone who needs to return to work as quickly as possible), and the patient's and clinician's preferences.

Noninvasive measures generally involve splinting of the metacarpophalangeal joint at 10 to 15 degrees of flexion with the proximal interphalangeal and distal interphalangeal joints free, for up to 6 weeks continuously [15]. This has been reported to be effective, although less so in the thumbs [16,17]. Also, splinting provides a reliable and functional

means of treating work-related trigger finger without loss of time from work [18]. Additional conservative treatment includes nonsteroidal anti-inflammatory drugs and avoidance of exacerbating activities, such as typing and repetitive gripping. Wearing padded gloves provides protection and may help decrease inflammation by avoiding direct trauma.

Rehabilitation

Rehabilitation may include treatment with an occupational or physical therapist experienced in the treatment of hand problems. Supervised therapy is generally not necessary but may be useful in the following scenarios: when a patient has lost significant strength, range of motion, or function from not using the hand or from prolonged splinting; when modalities such as ultrasound and iontophoresis are recommended to reduce inflammation; and when a customized splint is deemed to be necessary.

Therapy should focus on increasing function and decreasing inflammation and pain. This can be done by techniques such as ice massage, contrast baths, ultrasound, and iontophoresis with local steroid use. For someone with a very large or small hand or other anatomic variations (e.g., arthritic joints), a custom splint may fit better and allow him or her to function at work more easily than with a prefabricated splint. Range of motion and strength can be improved through supervised therapy either before surgery or postoperatively.

FIGURE 37.2 Under sterile conditions with use of a 27-gauge, $\frac{1}{2}$ -inch needle, a 2- to 3-mL aliquot of a local anesthetic and steroid mixture (e.g., 1 mL of 1% lidocaine mixed with 1 mL [40 mg] of methylprednisolone) is injected into the palm at the level of the distal palmar crease, which directly overlies the tendon. Before cleaning of the area to be injected, palpate for the nodule to localize exactly where the injection should be placed.

Procedures

A local corticosteroid injection combined with local anesthetic (Fig. 37.2) can be used as an alternative or in addition to other management [19,20]. A splint can be worn after the injection for a few days, purportedly to help protect the injected area. Because it may take 3 to 5 days for the medication to take effect, the patient should be advised to avoid activities with the affected hand as much as possible for 1 week after the injection.

The injections are usually beneficial and frequently curative [21,22]. Although the most recent Cochrane review found a clear benefit of corticosteroid injection over placebo [23], the reported success rates have varied widely. One study reported a treatment success of 54% and improvement rate of 88% at 1 year after a single injection [24]. This procedure is less effective with involvement of multiple digits (such as in patients with diabetes or rheumatoid arthritis) or when the condition has persisted longer than 4 months [22].

Surgery

In adults, steroid injections should be tried for most trigger finger cases before surgery is considered. However, surgical intervention is highly successful for conservative treatment failures and should be considered for patients desiring quick and definitive relief from this disability [25]. Individuals with diabetes, rheumatoid arthritis, multiple joint involvement, and younger age at onset are more likely to require surgery [2,26].

There are two general types of surgery for this condition: the standard open operative release of the A1 pulley and the percutaneous A1 pulley release procedure. In one

study using a percutaneous trigger finger release technique, the success rate was 100% at 12 weeks of follow-up [27]. Both surgical procedures are generally effective and carry a relatively low risk of complications [25,28].

Potential Disease Complications

Disease-related complications are rare and could include permanent loss of range of motion from development of a contracture in the affected finger, most commonly at the proximal interphalangeal joint [11]. More rarely, chronic intractable pain may develop despite treatment.

Potential Treatment Complications

Treatment-related complications from nonsteroidal anti-inflammatory drugs are well known and include gastric, renal, and hepatic side effects. Complications from local corticosteroid injections include skin depigmentation, dermatitis, subcutaneous fat atrophy, tendon rupture, digital sensory nerve injury, and infection [29,30]. Individuals with rheumatoid arthritis are more likely to have a tendon rupture [31]; therefore repeated injections are not recommended in these cases. Possible surgical complications include infection, nerve injury, and flexor tendon bowstringing [32–34].

CHAPTER 38

Ulnar Collateral Ligament Sprain

Sheila Dugan, MD

Sol M. Abreu Sosa, MD, FAAPMR

Synonyms

Skier's thumb
Ulnar collateral ligament tear or rupture
Gamekeeper's thumb
Break-dancer's thumb
Stener lesion [1] (ruptured, displaced ulnar collateral ligament with interposed adductor aponeurosis)

ICD-9 Code

842.00 Sprains and strains of hand and wrist

ICD-10 Codes

S63.90 Sprain of unspecified part of unspecified wrist and hand
S63.91 Sprain of unspecified part of right wrist and hand
S63.92 Sprain of unspecified part of left wrist and hand

Definition

The ulnar collateral ligament (UCL) complex includes the ulnar proper collateral ligament and the ulnar accessory collateral ligament [1]. These ligaments are located deep to the adductor aponeurosis of the thumb and stabilize the first metacarpophalangeal (MCP) joint. Tears can occur if a valgus force is applied to an abducted first MCP joint [2]. A lesion of the UCL is commonly called skier's thumb.

Acute injuries can occur when the strap on a ski pole forcibly abducts the thumb. In the United States, estimates for skiing injuries are 3 or 4 per 1000 skier-hours; thumb injuries account for about 10% of skiing injuries [3]. A study of downhill skiing found that thumb injuries accounted for 17% of skiing injuries, second only to knee injuries [4].

Three fourths of the thumb injuries were UCL sprains. UCL injury in football players may be related to falls or blocking. Other sports involving ball handling or equipment with repetitive abduction forces to the thumb, like basketball or lacrosse, can cause injury to the UCL.

UCL injuries may be accompanied by avulsion fractures. Complete tears can fold back proximally when they are ruptured distally and become interposed between the adductor aponeurosis [1]. This injury is known as the Stener lesion and has been described as a complication of complete UCL tears, with a frequency ranging from 33% to 80% [5].

Chronic ligamentous laxity is more common in occupational conditions associated with repetitive stresses to the thumb. The term *gamekeeper's thumb* was coined in the mid-1950s to describe an occupational injury of Scottish gamekeepers [6]. The term is also used for acute injuries to the UCL.

Rupture of the thumb MCP joint UCL represents one of the most common ligamentous injuries of the hand. Failure to recognize these injuries or to treat them appropriately can lead to instability, pain, and weakness of the joint [7].

Symptoms

Patients report pain and instability of the thumb joint. In the acute injury setting, patients can often recall the instant of injury. If the UCL is ruptured, patients report swelling and hematoma formation; pain may be minimal with complete tears. When pain is present, it can cause thumb weakness and reduced function. Numbness and paresthesias are not typical findings.

Physical Examination

The physical examination begins with the uninvolved thumb, noting the individual's normal range of motion and stability. Palpate to determine the point of maximal tenderness, assessing for distal tenderness; if the ligament is torn, it tears distally off the proximal phalanx. Initially, the examiner may be able to detect a knot at the site of ligament disruption. Laxity of the UCL is the key finding on examination. Ligament injuries are graded as follows: grade I sprains, local injury without loss of integrity; grade II sprains, local injury with partial loss of integrity, but end-feel is present; and grade III sprains, complete tear with loss of integrity and end-feel (Fig. 38.1). Passive abduction can be painful, especially in acute grade I and grade II sprains.

FIGURE 38.1 Skier's thumb. The ulnar collateral ligament to the metacarpophalangeal joint is disrupted by an abduction force. (From Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

The UCL should be tested with the first MCP joint in extension and flexion to evaluate all bands. The excursion is compared with the uninjured side. Testing for disruption of the ulnar proper collateral ligament is done with the thumb flexed to 90 degrees [1]. With the thumb in extension, a false-negative finding may result. The stability of the joint will not be impaired even if the ulnar proper collateral ligament is torn because of the taut ulnar accessory ligament in extension.

To avoid a false interpretation, the examiner must prevent MCP rotation by grasping the thumb proximal to the joint. If there is more than 30 degrees of laxity (or 15 degrees more laxity than on the noninjured side), rupture of the proper collateral ligament is likely. The thumb is then positioned in extension for repeated valgus stress testing. If valgus laxity is less than 30 degrees (or 15 degrees less than on the noninjured side), the accessory collateral ligament is intact. If valgus laxity is greater than 30 degrees (or 15 degrees more than on the noninjured side), the accessory collateral ligament is also ruptured [8].

A displaced fracture is a contraindication to stress testing. The fracture is manifested with swelling or discoloration on the ulnar side of the first MCP joint and tenderness along the base of the proximal phalanx. Some authors recommend that conventional radiographs be obtained before stressing of the UCL to determine whether a large undisplaced fracture is present because stress testing could cause displacement [9]. More than 3 mm of volar subluxation of the proximal phalanx indicates gross instability. The patient may be unable to pinch. Pain may limit the complete examination and lead to underestimation of injury extent. Infiltration of local anesthetic around the injury site can reduce discomfort and improve the accuracy of the examination [10].

Avulsion fracture represents a special class of collateral ligament injury. It cannot be graded I to III because technically the ligament is not torn. However, it still deserves mention because fracture can compromise the bone-ligament-bone stabilization complex and lead to chronic symptoms [11].

Functional Limitations

Individuals describe difficulty with pinching activities (e.g., turning a key in a lock). Injuries affecting the dominant hand can have an impact on many fine motor manipulations,

such as buttoning or retrieving objects from one's pocket. Injuries affecting the nondominant hand can impair bilateral hand activities requiring stabilization of small objects. Sports performance can be reduced with dominant hand injuries, and skiing, ball handling, or equipment use may be contraindicated in the acute stage of injury or on the basis of the extent of injury. In the setting of high-level or professional sports competition, the clinical decision to allow an athlete to compete with appropriate splinting or casting is based on severity of symptoms, with the caveat that the potential for worsening of the injury exists.

Diagnostic Studies

Whereas clinical examination is the mainstay of diagnosis, imaging studies are useful in the setting of uncertain diagnosis [12]. A plain radiograph is essential to rule out an avulsion fracture of the base of the ulnar side of the proximal phalanx. A stress film with the thumb in abduction is occasionally useful and should be compared with the uninjured side. UCL rupture presents with an angle greater than 35 degrees. Magnetic resonance imaging has greater than 90% sensitivity and specificity for UCL tears but is expensive and not always required [13].

Ultrasonography has been used as a less expensive means for diagnosis of UCL tears, but controversy exists as to whether it is useful or fraught with pitfalls [12,14–16]. However, a retrospective review of ultrasound studies from 17 surgically proven displaced full-thickness UCL tears identified the following ultrasound criteria for 100% accuracy in the diagnosis of a displaced full-thickness UCL tear: lack of UCL fibers and presence of a heterogeneous mass-like abnormality proximal to the MCP joint of the thumb. Such displaced UCL tears were most often located proximal to the leading edge of the adductor aponeurosis rather than superficially. Standardized ultrasound technique, which includes dynamic imaging, should be a consideration when the ultrasound examination is performed for this diagnosis [17].

Differential Diagnosis

Radial collateral ligament sprain or rupture
First MCP joint dislocation with or without volar plate injury
Thumb fracture-dislocation (Bennett fracture)

Treatment

Initial

Pain and edema are managed with ice, nonsteroidal anti-inflammatory drugs, and rest. Initial treatment of a first-degree (grade I) UCL sprain is taping for activity. Initial treatment of an incomplete (grade II) UCL sprain involves immobilization in a thumb spica cast for 3 to 6 weeks with the thumb slightly abducted. Injuries involving nondisplaced or small avulsion fractures associated with an incomplete UCL tear can also be managed nonsurgically and may require a longer course of immobilization. The cast may be extended to include the wrist for greater stability [18]. An alpine splint allows interphalangeal flexion while prohibiting abduction and extension of the first MCP joint [19]. A study of 63 cases of nonoperative and postsurgical patients compared short arm

plaster cast immobilization with functional splinting that prevented ulnar and radial deviation of the thumb; there was no difference between the two groups in regard to stability, thumb range of motion or strength, and length of sick leave after an average follow-up of 15 months [20]. Even slightly displaced avulsion fractures without complete UCL rupture tended to do well with immobilization in a study of 30 patients; those with larger bone fragments and larger initial rotation of the fragment were more likely to have residual symptoms [21].

Grade III injuries require surgical repair unless surgery is contraindicated for other reasons. Prompt referral for surgical consultation is recommended to maximize ligament positioning for reattachment. Failure to refer promptly or misdiagnosis of a complete tear can result in a less favorable outcome, including a Stener lesion [5].

Rehabilitation

Physical or occupational therapy is important in the rehabilitation management of UCL sprains. Therapists who have completed special training and are certified hand therapists (often called CHTs) can be great resources. Range of motion of the unaffected joints of the arm, especially the interphalangeal joint of the thumb, must be maintained. In the setting of a grade I sprain, after a short course of relative rest and taping, therapy may be required to restore strength to the preinjury level. In grade II sprains, a volar splint replaces the cast after 3 to 6 weeks. Splints may be custom molded by the therapist. They can be removed for daily active range of motion exercises. Passive range of motion and isometric strength training are initiated once pain at rest has resolved, and the patient is progressed to concentric exercise after about 8 weeks for nonsurgical lesions and 10 to 12 weeks for postsurgical lesions. Prophylactic taping is appropriate for transitioning back to sports-specific activity (Fig. 38.2). Postsurgical rehabilitation is less aggressive, with avoidance

FIGURE 38.2 Taping technique to protect the ulnar collateral ligament.

of strengthening, especially a power pinch, for 8 weeks postoperatively [22]. Protected early postoperative range of motion is indicated [23]. Full activity after grade II tears with or without nondisplaced avulsion fractures begins at 10 to 12 weeks compared with 12 to 16 weeks for surgically repaired injuries [24].

Procedures

There are no specific nonsurgical procedures performed for this injury.

Surgery

Early direct repair is required in the setting of a ruptured UCL (grade III) injury. Grade II and grade III injuries resulting in severe instability, displaced fractures, or intra-articular fragments are also surgical candidates. Surgery is indicated in the setting of gross instability [25]. Surgery is also indicated if the thumb is unstable in extension (more than 30 degrees of laxity or 15 degrees more laxity than on the noninjured side), which indicates a complete rupture, and ligament displacement is likely [8]. Tension wiring is used to fixate avulsions; open reduction may be required for large displaced avulsion defects. Surgical approaches that improve stability are the focus of new techniques [26,27]. However, postoperative immobilization is being reconsidered. A cadaver study concluded that a controlled active motion therapy protocol after suture anchor repair of a ruptured UCL is safe from a biomechanical point of view [28]. Reconstruction may be necessary for a chronic tear, including bone-retinaculum-bone reconstruction [29].

The techniques for reconstruction of chronic UCL injuries or gamekeeper's thumb involve either dynamic or static procedures. Dynamic procedures use musculotendinous units to stabilize the MCP joint by pulling the proximal phalanx ulnarward. Static procedures use free tendon grafts through bone tunnels or pull-out sutures to reconstruct the proper and accessory collateral ligaments. Static procedures have gained in popularity as they allow ligament reconstruction and preservation of existing thumb function, whereas dynamic procedures require the removal of existing muscle units and do not restore the anatomy of the ulnar collateral ligament [30].

Potential Disease Complications

Disease complications include chronic laxity with associated functional limitations, pain, and inability to pinch [31]; premature arthritis and persistent pain in the first MCP joint; and decreased range of motion of the thumb.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, renal, and hepatic systems. Prolonged splinting can lead to loss of range of motion of the joint and weakness and atrophy of the surrounding joints, depending on the extent of the injury and the length of time spent in a splint. Surgical risks include nonunion of avulsed fragments and the typical infrequent surgical complications, such as infection and

bleeding. Surgery can result in persistent numbness on the ulnar aspect of the thumb. A neurapraxia secondary to injury of the radial sensory nerve from either swelling or intraoperative traction is the most common nerve injury and usually resolves spontaneously [8,32].

CHAPTER 39

Ulnar Neuropathy (Wrist)

Ramon Vallarino, Jr., MD
Francisco H. Santiago, MD

Synonym

Guyon canal entrapment

ICD-9 Code

354.2 Lesion of ulnar nerve

ICD-10 Codes

G56.20 Lesion of ulnar nerve, unspecified upper limb

G56.21 Lesion of ulnar nerve, right upper limb

G56.22 Lesion of ulnar nerve, left upper limb

Definition

Entrapment neuropathy of the ulnar nerve can be encountered at the wrist in a canal formed by the pisiform and the hamate and its hook (the pisohamate hiatus). These are connected by an aponeurosis that forms the ceiling of Guyon canal (Fig. 39.1). This canal generally contains the ulnar nerve and the ulnar artery and vein. The following three types of lesions can be encountered [1].

Type I affects the trunk of the ulnar nerve proximally in Guyon canal and involves both the motor and sensory fibers. This is the most commonly seen lesion.

Type II affects only the deep (motor) branch distally in Guyon canal and may spare the abductor digiti quinti, depending on the location of its branching. A further classification is type IIa (still pure motor), in which all the hypothenar muscles are spared because of a lesion distal to their neurologic branching.

Type III affects only the superficial branch of the ulnar nerve, which provides sensation to the volar aspect of the fourth and fifth fingers and the hypothenar eminence. There is sparing of all motor function, although the palmaris brevis is affected in some cases. This is the least common lesion encountered.

This injury is commonly seen in bicycle riders and people who use a cane improperly because they place excessive weight on the proximal hypothenar area at the canal of Guyon and therefore are predisposed to distal ulnar nerve traumatic injury, especially affecting the deep ulnar motor branch (type II) [2,3]. Entrapment at Guyon canal has also been associated with prolonged, repetitive occupational use of tools, such as pliers and screwdrivers [2]. With the advancement of endoscopic carpal tunnel release during the past few years, there have been reports of both adverse and favorable consequences to the ulnar nerve at Guyon canal, which is very close anatomically. There have been inadvertent injuries to the ulnar nerve as well as documented decompression and improvement of nerve conduction [4,5].

Other rare causes have been reported in the literature. These include fracture of the hook of the hamate, ganglion cyst formation, tortuous or thrombosed ulnar artery aneurysm (hypothenar hammer syndrome), osteoarthritis or osteochondromatosis of the pisotriquetral joint, anomalous variation of abductor digiti minimi, schwannomas, aberrant fibrous band, and idiopathic [6–9].

Of 250 wrists studied by 3T magnetic resonance imaging assessment, it was noted that anatomy of the Guyon canal was normal in 168 (67.2%) wrists; 73 (29.2%) wrists presented with anatomic variations, and 9 (3.6%) wrists had derangements with clinical and radiologic features attributed to Guyon canal syndrome [10].

Symptoms

Signs and symptoms can vary greatly and depend on which part of the ulnar nerve and its terminal branches are affected and where along Guyon canal itself (Table 39.1). It is of great importance to be able to differentiate entrapment of the ulnar nerve at the wrist from entrapment at the elbow, which occurs far more commonly. The two clinical findings that confirm the diagnosis of Guyon canal entrapment instead of ulnar entrapment at the elbow are (1) sparing of the dorsal ulnar cutaneous sensory distribution in the hand and (2) sparing of function of the flexor carpi ulnaris and the two medial heads of the flexor digitorum profundus (Figs. 39.2 and 39.3). Otherwise, the symptoms in both conditions are generally similar and may include hand intrinsic muscle weakness and atrophy, numbness in the fourth and fifth fingers, hand pain, and sometimes severely decreased function.

FIGURE 39.1 Distal ulnar tunnel (Guyon canal) showing the three zones of entrapment. Lesions in zone 1 give motor and sensory symptoms, lesions in zone 2 cause motor deficits, and lesions in zone 3 create sensory deficits.

Table 39.1 Volar Forearm and Hand: Ulnar Nerve

Muscle	Action
Flexor carpi ulnaris	Flexes wrist, ulnarly deviates
Flexor digitorum profundus	Flexes distal interphalangeal joint (fourth and fifth)
Abductor digiti quinti*	Analogous to dorsal interosseous
Flexor digiti quinti*†	Analogous to dorsal interosseous
Opponens digiti quinti*†	Flexes and supinates fifth metacarpal
Volar interossei*	Adduct fingers, weak flexion metacarpophalangeal
Dorsal interossei*†	Abduct fingers, weak flexion metacarpophalangeal
Lumbricals (ring and fifth)*†	Coordinate movement of fingers; extend interphalangeal joints; flex metacarpophalangeal joints
Adductor pollicis*	Adducts thumb toward index finger
Lumbricals (ring, small)*	Coordinate movement of fingers; extend interphalangeal joints; flex metacarpophalangeal joints

*Hand intrinsic muscles.

†Hypothenar mass.

Physical Examination

Careful examination of the hand and a thorough knowledge of the anatomy of motor and sensory distribution of ulnar nerve branches are required to determine the location of the lesion. Except for the five muscles innervated by the median nerve (abductor pollicis brevis, opponens pollicis, flexor pollicis brevis

FIGURE 39.2 A, The flexor carpi ulnaris functions as a wrist flexor and an ulnar deviator. B, It can be tested by the patient's forcefully flexing (arrow) and ulnarly deviating the wrist. The clinician palpates the tendon while the patient performs this maneuver. (From Concannon MD: *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

superficial head, and first two lumbricals), the ulnar nerve supplies every other intrinsic muscle in the hand. Classically, there is notable atrophy of the first web space due to denervation of the first dorsal interosseous muscle (Fig. 39.4). In lesions involving the motor branches where the compression is in the proximal aspect of Guyon canal, there will be weakness and eventually atrophy of the interossei, the adductor pollicis, the fourth and fifth lumbricals, and the deep head of the flexor

FIGURE 39.3 A, Flexor digitorum profundus (arrows). B, These tendons can be tested by the patient's flexing the distal phalanx while the clinician blocks the middle phalanx from flexing. (From Concannon MD: *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

pollicis brevis. The palmaris brevis, abductor digiti quinti, opponens digiti quinti, and flexor digiti quinti may be involved or spared, depending on the level of the lesion.

Sensory examination in all but type II, in which the compression of the ulnar nerve is at the level of the lower wrist, reveals decreased sensation of the volar aspect of the

FIGURE 39.4 It is not unusual for patients with ulnar neuropathy to present with signs of muscle atrophy. It is most noticeable at the first web space, where atrophy of the first dorsal interosseous muscle leaves a hollow between the thumb and the index rays (arrow). (From Concannon MD: *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

FIGURE 39.5 Ulnar nerve lesion. A patient with an ulnar nerve lesion is asked to pull a piece of paper apart with both hands. Note that the affected side (right hand) uses the flexor pollicis longus muscle to prevent the paper from slipping out of the hand, thus substituting for the adductor pollicis muscle and generating the Froment sign. (From Haymaker W, Woodhall B. *Peripheral Nerve Injuries*. Philadelphia, WB Saunders, 1953.)

hypothenar eminence and the fourth and fifth fingers (with splitting of the fourth in most patients). There is always sparing of the sensation of the dorsum of the hand medially because it is innervated by the dorsal ulnar cutaneous branch of the ulnar nerve, which branches off the forearm proximal to Guyon canal [1]. The ulnar claw (hyperextension of the fourth and fifth metacarpophalangeal joints with flexion of the interphalangeal joints) seen in more proximal lesions may be more pronounced because of preserved function of the two medial heads of the flexor digitorum profundus. This creates flexion that is unopposed by the weakened interossei and lumbricals [1,11]. The flexor carpi ulnaris has normal strength. All the signs of intrinsic hand muscle weakness that are seen in more proximal ulnar nerve lesions, such as the Froment paper sign, are also found in Guyon canal entrapment affecting the motor nerve fibers (Fig. 39.5) [12]. Grip strength is invariably reduced in these patients when the motor branches of the ulnar nerve are affected [13].

Type III is the least common and involves pure sensory loss from the compression of the superficial branch at the distal aspect of Guyon canal.

Functional Limitations

Functional loss can vary from isolated decreased sensation in the affected region to severe weakness and pain with impaired hand movement and dexterity. As can be anticipated, lesions affecting motor nerve fibers are functionally more severe than those affecting only sensory nerve fibers. The patient may have trouble holding objects and performing many activities of daily living, such as occupation, daily household chores, grooming, and dressing. Vocationally, individuals may not be able to perform the basic requirements of their jobs (e.g., operating a computer or cash register, carpentry work). This can be functionally devastating.

Diagnostic Studies

The cause of the clinical lesion suspected after careful history and physical examination can be investigated with the use of imaging techniques. Plain radiographs could reveal a fracture of the hamate or other carpal bones as well as of the metacarpals and the distal radius, especially if there has been a traumatic injury. Magnetic resonance imaging [10] and computed tomography (multislice spiral computed tomographic angiography, multidetector computed tomography) can be helpful if a fracture, angioleiomyoma, tortuous ulnar artery, pseudoaneurysm of the ulnar artery, lipoma, or ganglion cyst is suspected [14–17]. As technology and accuracy of ultrasound equipment have advanced, there are now reports of the use of conventional and color duplex sonography to diagnose conditions such as thrombosed aneurysm of the ulnar artery [18,19].

Nerve conduction study and electromyography are helpful in confirming the diagnosis and the classification as well as in determining the severity of the lesion and the prognosis for functional recovery. Ulnar nerve entrapment in Guyon canal may be due to recurrent carpal tunnel syndrome [4]. As a rule, the dorsal ulnar cutaneous sensory nerve action potential is normal compared with the unaffected side [4]. Abnormalities in both sensory and motor conduction studies are seen in type I. The ulnar sensory nerve action potential recorded from the fifth finger is normal in type II, and an isolated abnormality is encountered in type III. The compound muscle action potential of the abductor digiti quinti is normal in types IIa and III. For this reason, it is important to perform motor studies recording from more distal muscles, such as the first dorsal interosseous [20]. Motor conduction studies should include stimulation across the elbow to rule out a lesion there, as it is far more common. Furthermore, ulnar nerve stimulation at the palm, after the traditional stimulation at the wrist and across the elbow, can be useful in sorting out the location of the compression and which fascicles are affected [21]. Care must be taken not to overstimulate because median nerve–innervated muscles are very close (i.e., lumbricals 1 and 2), and their volume-conducted compound muscle action potentials could confuse the diagnosis. A “neurographic” palmaris brevis sign has been described in type II ulnar neuropathy at the wrist [22]. This consists of a positive wave preceding the delayed abductor digiti minimi motor response, presumably caused by volume-conducted depolarization of a spared palmaris brevis muscle. Needle electromyography helps

in documenting axonal loss, determining severity of the lesion to allow prognosis for recovery, and more precisely localizing a lesion for an accurate classification. The flexor carpi ulnaris and the ulnar heads of the flexor digitorum profundus should be completely spared in a lesion at Guyon canal [23].

Differential Diagnosis [24]

- Ulnar neuropathy at the elbow (or elsewhere)
- Thoracic outlet syndrome (typically lower trunk or medial cord)
- Cervical radiculopathy at C8-T1
- Motor neuron disease
- Superior sulcus tumor (affecting the medial cord of the plexus)
- Camptodactyly (an unusual developmental condition with a claw deformity)

Treatment

Initial

Initial treatment involves rest and avoidance of trauma (especially if occupational or repetitive causes are suspected). Ergonomic and postural adjustments can be effective in these cases. The use of nonsteroidal anti-inflammatory drugs in cases in which an inflammatory component is suspected can also be beneficial. Analgesics may help control pain. Low-dose tricyclic antidepressants may be used both for pain and to help with sleep. More recently, the use of antiepileptic medications for neuropathic pain syndromes has been increasing because of good efficacy. Prefabricated wrist splints may be beneficial and are often prescribed for night use. For individuals who continue their sport or work activities, padded, shock-absorbent gloves may be useful (e.g., for cyclists, jackhammer users).

Rehabilitation

A program of physical or occupational therapy performed by a skilled hand therapist can help obtain functional range of motion and strength of the interossei and lumbrical muscles. Instruction of the patient in a daily routine of home exercises should be done early in the diagnosis. Static splinting (often done as a custom orthosis) with an ulnar gutter will ensure rest of the affected area. In more severe cases, the use of static or dynamic orthotic devices may be considered to improve the patient's functional level. Weakness in the ulnar claw deformity can be corrected to improve grasp with the use of a dorsal metacarpophalangeal block (lumbrical bar) to the fourth and fifth fingers with a soft strap over the palmar aspect [25].

A work site evaluation may be beneficial as well. Ergonomic adaptations can prove helpful to individuals with ulnar nerve entrapment at the wrist (e.g., switching to a foot computer mouse or voice-activated computer software).

Procedures

Injections into Guyon canal may be tried if a compressive entrapment neuropathy is suspected and generally provide symptomatic relief (Fig. 39.6) [2].

FIGURE 39.6 Approaches for two ulnar nerve blocks. The needle with syringe attached demonstrates the puncture for block at Guyon canal. The circle is over the pisiform bone, and the solid mark is over the hook of the hamate. The second needle demonstrates the puncture site for an ulnar nerve block at the wrist, ulnar approach. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

Under sterile conditions, with use of a 25-gauge, 1½-inch disposable needle, a mixture of corticosteroid and 1% or 2% lidocaine totaling no more than 1 mL is injected into the distal wrist crease to the radial side of the pisiform bone; the needle is angled sharply distally so that its tip lies just ulnar to the palpable hook of the hamate [2,26]. Postinjection care includes ensuring hemostasis immediately after the procedure, local icing for 5 to 10 minutes, and instructions to the patient to rest the affected limb during the next 48 hours.

Surgery

Surgery is recommended when there is a fracture of the hook of the hamate or of the pisiform or a tortuous ulnar artery that causes neurologic compromise. Ganglion cyst and pisohamate arthritis are also indications for surgical treatment. Surgery in general involves exploration, excision of the hook of hamate or pisiform (if fractured), repair of the ulnar artery as necessary, decompression, and neurolysis of the ulnar nerve [2,6]. Experience and a sound knowledge of the possible anatomic variations (i.e., muscles, fibrous bands) and the arborization patterns of the ulnar artery in Guyon canal are of great importance in promoting a positive outcome when surgery is medically necessary [8,27].

Preoperatively, the patient is educated about the expected clinical course after nerve release. The patient is warned about incisional tenderness for 8 to 12 weeks postoperatively. Nighttime numbness, weakness, or clumsiness will resolve gradually, and recovery may be incomplete.

For days 0 to 5, the patient is instructed in isolated tendon glide exercises for all digits. No heavy resistance activities are permitted for 6 weeks after surgery. From 1 to 6 weeks, active range of motion of the wrist, edema control, scar massage, and desensitization are initiated when the

incision is made accessible. From 6 to 12 weeks, progressive strengthening exercises are initiated [28].

Potential Disease Complications

The severity and type of lesion of the ulnar nerve at the wrist will ultimately determine the complications. Severe motor axon loss will cause profound weakness and atrophy of ulnar-innervated muscles in the hand and render the patient unable to perform even simple tasks because of lack of vital grip strength. Some patients also have chronic pain in the affected hand, which can be severely debilitating, perhaps inciting a complex regional pain syndrome, and it can predispose them to further problems, such as depression and drug dependency.

Potential Treatment Complications

The use of nonsteroidal anti-inflammatory drugs should be carefully monitored because there are potential side effects, including gastrointestinal distress and cardiac, renal, and hepatic disease. Low-dose tricyclic antidepressants are generally well tolerated but may cause fatigue, so they are usually prescribed for use in the evening. Injection complications include injury to a blood vessel or nerve, infection, and allergic reaction to the medication used. Complications after surgery include infection, wound dehiscence, recurrence, and, rarely, complex regional pain syndrome.

Definition

Osteoarthritis of the wrist refers to the painful degeneration of the articular surfaces that make up the wrist due to noninflammatory arthritides. It commonly affects the joints between the distal radius and the proximal row of carpal bones. Symptoms include pain, swelling, stiffness, and crepitation. Radiographs will reveal different degrees of joint space narrowing, cyst formation, subchondral sclerosis, and osteophyte formation.

Secondary osteoarthritis resulting from post-traumatic conditions, as can be seen after distal radius fractures, carpal fractures, and carpal instability, is the most common form [1]. Primary osteoarthritis in the wrist is rare. The Framingham study showed a 9-year incidence of only 1% of radiographically significant wrist osteoarthritis in women and 1.7% in men. These rates are significantly lower than the rates of thumb basal joint osteoarthritis (30%), distal interphalangeal joint arthritis (28%-35% in patients older than 40 years), and radiographic hand osteoarthritis in patients 80 years and older (90%-100%) [2]. Rare conditions that may cause wrist osteoarthritis include idiopathic osteonecrosis of the lunate (Kienböck disease) and the scaphoid (Preiser disease). Distal radius fractures that have healed inappropriately (malunited) can also be the cause (Fig. 40.1). In considering malunited fractures of the distal radius, abnormal parameters that have been shown to

FIGURE 40.1 Wrist osteoarthritis secondary to a malunited wrist fracture. Note the dorsal angulation of the distal articular surface and the reduced joint space. This patient also had significant osteopenia secondary to pain-induced lack of use.

be associated with wrist arthritis include the following: on an anteroposterior radiograph, an intra-articular step-off of more than 2 mm and radial shortening of more than 5 mm; and on the lateral radiograph, a dorsal angulation of more than 10 degrees [3–5].

Carpal fractures that fail to heal, particularly of the scaphoid, can also be the cause of arthritis [6]. This bone is predisposed to nonunions biologically because of its fragile vascular supply and biomechanically because of the shear forces it encounters [7,8]. Other factors associated with nonunions include fracture displacement, fracture location, and delay in initiation of treatment [9,10]. Features of a scaphoid nonunion that appear to be associated with arthritis are the displacement of the cartilaginous surfaces and the loss of carpal stability [11,12]. Both of these lead to abnormal loading of the cartilage and consequently to ensuing arthritis. This pattern of arthritis is known as scaphoid nonunion advanced collapse (SNAC) (Fig. 40.2).

Carpal instability can also result in uneven loading of the articular surfaces and subsequent arthritis [13] (Figs. 40.3 and 40.4). The most common form of carpal instability is scapholunate dissociation [14]. It consists of a disruption of the interosseous ligament between the scaphoid and lunate. The resultant abnormal biomechanics lead to abnormal loading and subsequent arthritis, a pattern known as scapholunate advanced collapse [1] (SLAC).

FIGURE 40.2 Osteoarthritic change of a wrist with a scaphoid nonunion (SNAC), stage 2. Notable features include the “beaked” appearance of the radial styloid, cystic change along with a nonunion in the scaphoid, and “kissing” osteophytes on adjoining surfaces of the radius and scaphoid.

Symptoms

Wrist pain is the presenting symptom in the overwhelming majority of patients. For the most part, this pain is of insidious onset, although many patients will recall a particular event that brought it to their attention. It is diffusely located across the dorsum of the wrist. It may be activity related and may bear little correlation to radiographic findings. Patients may also report inability to do their daily activities because of weakness, but on further questioning, this weakness is often secondary to pain.

Another presenting symptom is stiffness, particularly in flexion and extension of the wrist. Pronation and supination are usually not affected, unless the arthritic process is extensive and also involves the distal radioulnar joint. Motion may also be associated with a clicking sensation or with audible crepitation.

Complaints about cosmetic deformity are also common, particularly after distal radius fractures that have healed with an inappropriate alignment. Swelling is also commonly noted by the patients. This swelling is essentially a representation of the malunited fracture, but in patients with advanced arthritis irrespective of the etiology, it may represent synovial hypertrophy or osteophyte formation. In this situation, the swelling tends to be located in the dorsoradial region of the wrist (Fig. 40.5).

Physical Examination

Examination of the wrist includes a thorough examination of the entire upper limb. Comparison with the opposite side is useful to determine the degree of motion loss, if any. In wrist osteoarthritis, the most obvious finding may be loss of motion. Normal range of motion includes approximately 80 degrees of flexion, 60 degrees of extension, 20 degrees of radial deviation, and 40 degrees of ulnar deviation [15]. Comparison with the opposite side, if it is not involved, is useful to determine the degree of motion loss.

FIGURE 40.3 A and B, Wrist osteoarthritis secondary to scapholunate advanced collapse (SLAC), stage 2. Note the increased scapholunate space and the sclerosis of the radioscaphoid joint. Early osteophytes are clearly seen on the radial border of the scaphoid. The lateral view shows dorsal osteophytes as well as the dorsally angled lunate.

FIGURE 40.4 A and B, Advanced wrist osteoarthritis secondary to SLAC (stage 3). Note the increased scapholunate space, the sclerosis in the radioscaphoid and lunocapitate joints, and the proximal migration of the capitate. Most notable in both views is the complete loss of normal wrist alignment.

The wrist is palpated for evidence of cysts or tenderness. Tenderness just distal to Lister tubercle may be a sign of pathologic change at the scapholunate joint, including scapholunate dissociation, Kienböck disease, or synovitis of the radiocarpal joint. Tenderness at the anatomic snuffbox may indicate a

scaphoid fracture or nonunion and, in early SNAC wrists, may be the site of radioscaphoid degeneration. In the presence of pancarpal arthritis, the tenderness is usually diffuse.

Provocative maneuvers should also be performed to check for signs of carpal instability. The scaphoid shift test

FIGURE 40.5 Clinical appearance of an osteoarthritic wrist that in this particular instance was secondary to a scaphoid nonunion. The diffuse radiodorsal swelling indicates some degree of synovitis.

of Watson evaluates for scapholunate instability [16]. In this test, the examiner places a thumb volarly on the patient's scaphoid tubercle, and the rest of the fingers wrap around the wrist to lie dorsally over the proximal pole of the scaphoid. As the wrist is taken from ulnar deviation to radial deviation, the thumb will apply pressure on the scaphoid tubercle and force the scaphoid to sublux out of its fossa dorsally in ligamentously lax patients as well as in those with frank scapholunate instability. Once pressure from the thumb is released, the scaphoid will then shift back into its fossa. This finding is best demonstrated in those who have ligamentous laxity or those with recent injuries. Patients who have chronic injuries often develop sufficient fibrosis to prevent subluxation of the scaphoid out of its fossa. However, they often still have pain that is reproduced with this maneuver. Comparison with the unaffected side is essential, especially if the patient has evidence of generalized ligamentous laxity.

The strength of the abductor pollicis brevis is tested by asking the patient to palmar abduct the thumb against resistance, and it should be compared with the opposite side. Similarly, the strength of the first dorsal interosseus should be checked by asking the patient to radially deviate the index finger against resistance. These tests evaluate for motor deficits of the median nerve and ulnar nerve, respectively. Sensation should also be compared with the opposite side. Whereas static two-point discrimination is an excellent way to test sensation in the office, a more precise evaluation of early sensory deficits can be performed by graduated Semmes-Weinstein monofilaments. Frequently, this test requires a referral to occupational therapists who perform it.

Functional Limitations

The majority of the limitations in wrist arthritis arise from a lack of motion. A range of motion from 10 degrees of flexion to 15 degrees of extension is required for activities involving personal care [17]. The loss of motion mainly affects activities of daily living such as washing one's back, fastening a brassiere, and writing. Eating, drinking, and using a telephone require 35 degrees of extension. However, learned compensatory maneuvers can allow most activities

of daily living to be accomplished with as little as 5 degrees of flexion and 6 degrees of extension [18].

Diagnostic Studies

The initial evaluation of the arthritic wrist includes standard posteroanterior, lateral, and pronated oblique radiographs. In the posteroanterior view, any evidence of arthritis between the radius and proximal row of carpal bones or between the proximal and distal rows should be noted. Radiographic features that indicate an arthritic process include reduction or loss of joint space, osteophyte formation, cyst formation in periarticular regions, and loss of normal bone alignment (see Figs. 40.2 to 40.4).

Injury to the scapholunate ligament is evidenced by a space between the scaphoid and the lunate greater than 2 mm and a cortical ring sign of the scaphoid [14]. Sclerosis or collapse of the lunate is consistent with Kienböck disease [19]. The lateral view can reveal signs of carpal instability, such as a dorsally or palmarly oriented lunate. An angle between the scaphoid and the lunate in excess of 60 degrees is also consistent with scapholunate dissociation. The oblique view will often demonstrate the site of a scaphoid nonunion. Although it may be possible to make a diagnosis of scapholunate dissociation on plain radiographs, some patients can often have bilateral scapholunate distances and angles in excess of normal limits. It is therefore critical to obtain contralateral radiographs before a diagnosis of scapholunate injury is made.

Patterns of arthritic progression in SLAC and SNAC wrists have been classified into three stages. In a SLAC wrist, stage 1 involves arthritis between the radial styloid and the distal pole of the scaphoid; stage 2 results in reduction or loss of joint space between the radius and the proximal pole of the scaphoid (see Fig. 40.3), and stage 3 indicates capitulate degeneration with proximal migration of the capitate between the scaphoid and lunate (see Fig. 40.4). In a SNAC wrist, stage 1 and stage 3 are similar to those in a SLAC wrist. However, in stage 2, there is degenerative change between the distal pole of the scaphoid and capitate (see Fig. 40.2).

Other imaging modalities are not necessary for the diagnosis of osteoarthritis. Computed tomography is sometimes used to evaluate the alignment of the scaphoid fragments in cases of nonunion and the amount of collapse of the lunate in Kienböck disease. Magnetic resonance imaging is occasionally used to evaluate the vascularity of the scaphoid proximal pole and lunate in scaphoid nonunions and Kienböck disease, respectively [19,20]. Wrist arthroscopy offers the optimal ability to assess the condition of the articular cartilage; however, this assessment can be made from plain radiographs or at the time of surgical reconstruction of the wrist.

Differential Diagnosis

- Acute fracture
- Septic arthritis
- Crystalline arthritis
- Carpal tunnel syndrome
- Rheumatoid arthritis
- de Quervain tenosynovitis

Treatment

Initial

Osteoarthritis of the wrist is a condition that has usually been present for a significant amount of time. However, it is not uncommon for symptoms to be of a short duration, and they can often be manifested after seemingly trivial trauma. It is important for the physician to establish good rapport with the patient during several visits so that the pathophysiologic changes of the process can be emphasized to the patient. This becomes even more important in situations involving workers' compensation or litigation or both. It is also important for the patient to understand that the condition cannot be reversed and that the symptoms are likely to be cyclic. Patients must understand that over time, the condition may worsen radiographically; however, it is impossible to predict the rate of progression or severity of symptoms that might ensue.

Many patients present with symptoms of wrist osteoarthritis that are not severe enough to be limiting but enough to be noticed. These patients are often looking for reassurance about their condition. If they are able to do all the activities that they want to do, intervention is not needed. They should not refrain from doing their activities in fear that they may accelerate the condition; there is no scientific evidence to substantiate this concern. This approach offers the least amount of risk to the patient.

Other patients may prefer to have some symptom reduction, particularly during episodes of acute worsening, despite some inconvenience or small risks. An over-the-counter wrist splint with a volar metal stabilizing bar (cock-up splint) can be a small inconvenience; however, by virtue of immobilizing the wrist, it can provide great symptom relief during daily activities. This metal bar can be contoured to place the wrist in the neutral position rather than in extension, as most splints of this nature tend to do. The neutral position appears to be better tolerated by patients and affords better compliance with splint wear. Both over-the-counter and custom leather splints have been shown to relieve pain and to improve function and grip strength. Custom splints, however, provided more of these improvements and were better liked by patients in one study [21]. Nonsteroidal anti-inflammatory drugs can also provide significant pain relief, particularly during periods of acute exacerbation of symptoms. A long-term use of nonsteroidal anti-inflammatory drugs is not indicated. Periodic application of ice, especially during periods of acute symptom exacerbation, can be of help. On occasion, in patients with radioscaphoid arthritis (SNAC), inclusion of the thumb in a custom-made orthoplast splint may provide better pain relief. Use of magnetic and copper bracelets has not been shown to be effective in clinical trials [22].

Rehabilitation

Once the acute inflammation phase has passed, most patients are able to resume most activities. Some may complain of persistent lack of motion or strength. These patients may benefit from a home exercise program for range of motion and strengthening directed by an occupational therapist. Modalities such as fluidized therapy may help with range of motion. Static progressive splinting is usually not recommended to improve range of motion because there is often a bone block to motion.

It is always important to understand that therapy itself may worsen symptoms, especially passive stretching exercises. Active range of motion and active-assisted range of motion exercises are better tolerated by patients, and some patients may be better off without any formal rehabilitation.

Procedures

Nonsurgical procedures, including corticosteroid injections, may be indicated for wrist osteoarthritis, although they appear to have a greater use in crystalline and inflammatory arthritides. Hyaluronan injections for osteoarthritis have been studied in other joints, including the thumb carpometacarpal joint, with beneficial results; however, their use in the wrist is still considered experimental [23]. Typically, all injections around the wrist should be done by aseptic technique with a 25-gauge, 1½-inch needle and a mixture of a nonprecipitating, water-soluble steroid preparation that is injected along with 2 mL of 1% lidocaine.

The radiocarpal joint can be injected from the dorsal aspect approximately 1 cm distal to Lister tubercle, with the needle angled proximally about 10 degrees to account for the slight volar tilt of the distal radius articular surface. This is done with the wrist in the neutral position. Gentle longitudinal traction by an assistant can help widen the joint space, which may be reduced on account of the disease. An alternative radiocarpal injection site is the ulnar wrist, just palmar to the extensor carpi ulnaris tendon at the level of the ulnar styloid process. With strict aseptic technique, a 25-gauge, 1½-inch needle is inserted into the ulnocarpal space, just distal to the ulnar styloid, just dorsal or volar to the easily palpable tendon of the extensor carpi ulnaris. The needle must be angled proximally by 20 to 30 degrees to enter the space between the ulnar carpus and the head of the ulna. It is important to ascertain that the injectate flows freely. Any resistance indicates a need to reposition the needle appropriately. Alternatively, the injection may be performed by fluoroscopic guidance with the help of a mini image intensifier, if one is available in the office.

If a midcarpal injection is required, this is done through the dorsal aspect, under fluoroscopic guidance, with injection into the space at the center of the lunate-triquetrum-hamate-capitate region.

Surgery

The goal of surgery in an osteoarthritic wrist is pain relief. Surgical procedures for osteoarthritis can be divided into motion-sparing procedures and fusions (arthrodesis). However, even motion-sparing procedures often result in significant loss of motion. This is very important in patients who have almost no motion preoperatively. These patients will not benefit from motion-sparing procedures and are better served with total wrist fusions. The decision to proceed with surgery should not be made until nonsurgical means have been tried for an adequate time, which usually amounts to a period of 3 to 6 months. In some patients who are going to have a total wrist fusion, before a decision is made about surgery, it is useful to apply a well-molded fiberglass short arm cast for 2 weeks to accustom the patient to the lack of wrist motion.

Motion-sparing procedures include proximal row carpectomy, total wrist arthroplasty, and limited intercarpal fusions with scaphoid excision. The excision of the scaphoid is essential

because 95% of wrist arthritis involves the scaphoid [1]. Proximal row carpectomy involves removal of the scaphoid, lunate, and triquetrum. The capitate then articulates with the radius through the lunate fossa (Fig. 40.6). Wrist stability is maintained by preserving the volar wrist ligaments. As a prerequisite for this procedure, the lunate fossa of the radius and the articular surface over the head of the capitate must be healthy and free of degenerative change (Fig. 40.7). The main advantage of this procedure is that it does not involve any fusions. After a short period of postoperative casting, patients are allowed to start moving the wrist as early

as 3 weeks after surgery. Most people are able to attain a flexion-extension arc of 60 to 80 degrees and 60% to 80% of the grip strength of the uninvolved side [24,25] (Fig. 40.8). This procedure is appropriate for the early stages of SLAC and SNAC arthritis. Some surgeons have attempted to

FIGURE 40.6 A and B, Plain radiographs of the patient seen in Figure 40.3 after she underwent a proximal row carpectomy. A terminal radial styloidectomy has also been performed to reduce impingement of the trapezium on the tip of the radius. Note how well the capitate articulates with the lunate fossa of the distal radius.

FIGURE 40.7 An intraoperative photograph of the patient seen in Figures 40.3 and 40.6, during a proximal row carpectomy, to show healthy articular cartilage over the head of the capitate.

FIGURE 40.8 A and B, Postoperative function 6 months after a proximal row carpectomy. The patient has recovered nearly a 100-degree arc of motion and has no pain.

extend the indications for proximal row carpectomy in the setting of capitate head cartilage loss or lunate fossa arthrosis by suggesting interposition of soft tissue allograft or autograft or osteochondral autograft to the capitate from the excised carpal bones [26–28].

Indications for total wrist arthroplasty have expanded from end-stage rheumatoid arthritis to include post-traumatic osteoarthritis, end-stage primary osteoarthritis, and Kienböck disease. Patients are discouraged from heavy lifting after arthroplasty surgery but can otherwise return to full activity after a 2- to 3-month period of splinting in 30 to 40 degrees of extension to prevent flexion contracture. Short-term results have been encouraging with significant pain relief, maintenance of grip strength of 60% of the uninvolved side, preservation of motion, and even an increase in radial deviation in one study [29,30]. Total wrist arthroplasty is not recommended in people younger than 50 years, heavy laborers, or those dependent on walking aids.

The most common limited intercarpal fusion is known as the four-corner or four-bone fusion. It involves creating a fusion mass between the lunate, triquetrum, capitate,

and hamate. The scaphoid is excised. The prerequisite for this procedure is an intact joint between the radius and the lunate. A theoretical advantage of this procedure over a proximal row carpectomy is that it maintains carpal height, leading to a better grip strength (Fig. 40.9). However, this has not been shown to be the case in larger studies comparing these two procedures. The flexion-extension arc of wrist motion is also not significantly different between these two procedures [31]. Theoretical disadvantages of a four-corner fusion include protracted immobilization until fusion is confirmed (usually 8 weeks) and the possibility of needing a secondary operative procedure to remove hardware (Fig. 40.10). This procedure is also appropriate for the early stages of SLAC and SNAC arthrosis.

Patients with severe arthrosis that involves not only the radiocarpal joint but also the joint between the proximal and distal carpal rows (midcarpal joint) are better served with total wrist fusion. This procedure is also beneficial in patients who present preoperatively with minimal or no wrist motion. It involves a fusion between the radius, proximal row, and distal row of carpal bones. The wrist is

FIGURE 40.9 A and B, Postoperative radiographs after scaphoid excision and four-bone fusion have been performed.

FIGURE 40.10 A and B, A mature four-bone fusion after a secondary procedure to remove the pins seen in Figure 40.9. To avoid the second operative procedure, some may elect to leave the pins percutaneous and to remove them during an office visit.

protected with a splint for 4 to 6 weeks. Most patients are able to attain a grip strength that is 60% to 80% of the opposite side [32]. A successful fusion abolishes the flexion-extension arc of wrist motion and, more important, can be effective in obtaining pain relief. However, the lost motion makes it difficult for patients to position the hand in tight spaces and can affect perineal care [31]. In these patients, the loss of motion does not appear to have an adverse functional impact because most of these patients have significant reduction of motion at the time of presentation. The pain relief provided by this procedure, however, can have a positive impact on functional outcome to a significant degree. Pronation and supination are unaffected. This procedure is appropriate for the advanced stages of SLAC and SNAC arthritis (Fig. 40.11).

Wrist denervation, which does not address the osteoarthritis directly but acts as a palliative option, was proposed in 1965 by Wilhelm [33]. The procedure involves ablation of sensory branches of local nerves to the wrist capsule without addressing any bone deformity. Since then, others have modified the approach and have also suggested partial denervations. Pain relief can be as high as 80% to 100%. The major benefit of denervation is that all the other options

remain at the surgeon's disposal should bone procedures become necessary. Despite early concerns, the wrist does not undergo Charcot arthropathy after denervation [34,35].

Potential Disease Complications

Wrist osteoarthritis that progresses to advanced stages results in severely painful limitation of motion. Patients are unable to do their activities of daily living because any load across the arthritic wrist joint results in pain. The pain and stiffness can also inhibit the ability of the patient to position the hand in space. Rarely, osteophytes occurring over the dorsal aspect of the distal radius and the distal radioulnar joint can cause attritional ruptures of extensor tendons.

Potential Treatment Complications

Nonsteroidal anti-inflammatory medicines carry risks to the cardiovascular, gastric, renal, and hepatic systems. For these reasons, these medications are typically used for short periods. Surgery exposes the patient to significant risks from anesthesia, infection, nerve injury, and tendon injury. Fusions carry the risk of nonunion and malunion as well as that of hardware complications, such as prominence of the hardware, tendon irritation, and metal sensitivity. Motion-sparing procedures can eventually lead to further degenerative disease (Fig. 40.12) and in the presence of symptoms may require further surgery, which most commonly consists of a total wrist fusion. Total wrist arthroplasties can be complicated by infection, loosening, wound issues, hardware failure, instability, dislocation, tendon rupture, and impingement, with complication rates varying from 9% to 75%. Survival rates of total wrist arthroplasty in a Norwegian study ranged from 57% to 78% at 5 years and were as high as 71% at 10 years, depending on the implant and preoperative diagnosis [30].

FIGURE 40.11 A and B, A total wrist arthrodesis with a contoured plate and screws. In the anteroposterior radiograph, it is evident that the wrist is in mild ulnar deviation; in the lateral radiograph, the wrist appears to be in mild dorsiflexion. This is the optimal position for hand function in such patients. The patient also underwent excision of the distal ulna.

FIGURE 40.12 Advanced degenerative disease in a patient who underwent a proximal row carpectomy a few years before. Despite the radiographic appearance, the patient reported only mild pain.

Definition

Rheumatoid arthritis is a systemic autoimmune disorder involving the synovial joint lining and is characterized by chronic symmetric erosive synovitis. It has been estimated that 1% to 2% of the world's population is affected by this disorder. Women are affected more frequently with a ratio of 2.5:1. The cause of rheumatoid arthritis is thought to be multifactorial, including both genetic and environmental factors. The diagnostic criteria for rheumatoid arthritis include symptoms (morning stiffness, symmetric joint swelling, and skin nodules), laboratory test results, and radiographic findings. The wrist is among the most commonly involved peripheral joints; more than 65% of patients have some wrist symptoms within 2 years of diagnosis, increasing to more than 90% by 10 years. Of patients with wrist involvement, 95% have bilateral involvement [1–5].

The inflamed and hypertrophied synovial tissue is responsible for the destruction of adjacent tissues and resultant deformities. The cascade of events that lead to articular cartilage damage is a T cell-mediated autoimmune process mediated by the HLA class II locus [4,5]. The synovium is infiltrated by destructive molecules, resulting in thickening and proliferation of the synovium, chemotactic attraction of polymorphonuclear cells, and release by the polymorphonuclear cells of lysosomal enzymes and free oxygen radicals, which destroy joint cartilage.

The wrist articulation can be divided into three compartments, all of which are lined by synovium and therefore involved in rheumatoid arthritis: the radiocarpal, midcarpal, and distal radioulnar joints. Cartilage loss from both degradation and synovial proliferation contributes to ligamentous laxity of the extrinsic and intrinsic wrist ligaments. The laxity around the wrist leads to the classic rheumatoid deformities of carpal supination and ulnar translocation. The normally stout volar radioscaphocapitate ligament and the dorsal radiotriquetral ligament, which are important stabilizers of the carpus in relation to the distal radius, are stretched, resulting in ulnar translocation of the carpus. Laxity of the volar radioscaphocapitate ligament leads to loss of the ligamentous support to the waist of the scaphoid as well as weakening of the intrinsic scapholunate ligament. The scaphoid responds by adopting a flexed posture, and this is accompanied by radial deviation

of the hand at the radiocarpal articulation. The bony carpus supinates and subluxes palmarly and ulnarly; thus, the ulna is left relatively prominent on the dorsal aspect of the wrist, a condition sometimes referred to as the *caput ulnae* syndrome [5–7]. The secondary effect of carpal supination is subluxation of the extensor carpi ulnaris tendon in a volar direction to the point that it no longer functions effectively as a wrist extensor. The bony architecture of the wrist is affected secondarily, in that the inflammatory cascade also stimulates bone-resorbing osteoclasts, which cause subchondral and periarticular osteopenia.

Areas of the wrist that display vascular penetration into bone or contain significant synovial folds, such as the radial attachment of the radioscaphocapitate ligament (the most radial of the volar radiocarpal ligaments), the waist of the scaphoid, and the base of the ulnar styloid (prestyloid recess), are the most common sites of progressive synovitis. The results of chronic erosive changes in these areas are bone spicules that can abrade and weaken tendons passing in their immediate vicinity, ultimately causing tendon rupture and functional deterioration. The extensor tendons to the small finger and ring finger (Vaughn-Jackson syndrome) [8], which rupture at the level of the ulnar head (see *caput ulnae* syndrome earlier), and the flexor tendon of the thumb at the level of the scaphoid (Mannerfelt syndrome) [9] are the most commonly involved. In addition to mechanical abrading, the extensor tendons are enclosed in a sheath of synovium at the wrist, which makes them susceptible to the damaging changes of synovial hypertrophy that is commonly

seen in rheumatoid arthritis. The synovial proliferation causes changes in tendons of both an ischemic and inflammatory nature, which make them susceptible to weakening and eventual rupture.

Symptoms

Three distinct areas of the wrist can be the source of symptoms from rheumatoid disease: the distal radioulnar joint, the radiocarpal joint, and the extensor tendons. However, symptoms can originate as far proximal as the cervical spine or involve the shoulder and the elbow. Joint-related symptoms in early disease include swelling and pain, with morning stiffness as a classic characteristic. Loss of motion in the early stages usually results from synovial hypertrophy and pain. Progressive loss of motion is seen with disease progression and represents articular destruction. The distal radioulnar joint can be painful because of inflammation within the joint, and it can be a source of decreased forearm rotation (Figs. 41.1 and 41.2). Later stages of the disease usually are manifested with complaints of severe pain, decreased motion, significant cosmetic concerns, and difficulties in performing activities of daily living. Erosive changes are more strongly associated with changes in subjective disability than joint space narrowing is [10].

Tenosynovitis of the tendons traversing the dorsal wrist can often be manifested as a painless swelling. Patients with advanced rheumatoid disease in the wrist or those unresponsive to medical management may present with loss of

FIGURE 41.1 A, Appearance of the wrist in early rheumatoid arthritis. Note the swelling around the ulnar head. B, The synovial hypertrophy around the head of the ulna and distal radioulnar joint is appreciated in profile. There is also an early radial deviation of the hand at the wrist. C, The prominence of the ulnar head is compounded by the subluxation and supination of the carpus, creating an appearance of an abrupt change in contour from the wrist to the hand.

FIGURE 41.2 A, Synovitis around the distal end of the ulna may be manifested with swelling just volar to the ulnar styloid, as in this patient. B and C, Loss of motion in early rheumatoid disease of the wrist, as in this patient, is often a manifestation of the synovitis and pain associated with it rather than a true joint destruction.

extension of the digits at the metacarpophalangeal joints or with inability to flex the thumb at the interphalangeal articulation. These findings result from extensor digitorum communis tendon ruptures over the dorsal aspect of the wrist or a rupture of the flexor pollicis longus over the volar scaphoid as described before. Deformity of the wrist and hand is often the most concerning factor for patients and is attributable to the progressive carpal rotation and translocation discussed earlier, coupled with the extensor tendon imbalance accentuated at the metacarpophalangeal joints of the hand, which causes ulnar drift of the digits. The compensatory ulnar deviation occurs at the metacarpophalangeal joints, and it can often be the presenting symptom in undiagnosed or untreated patients.

Symptoms of median nerve compression and dysfunction (altered or absent sensation primarily in the radially sided digits and night pain and paresthesias in the hand) can be associated with rheumatoid arthritis as well. This is primarily due to hypertrophy of the tenosynovium around the flexor tendons within the confined space of the carpal canal, with resulting compression of the median nerve. Vascular damage of the peripheral nerve (rheumatoid neuropathy) may also contribute to symptoms [11].

Physical Examination

Keeping in mind the three primary locations of rheumatoid involvement in the wrist, careful physical examination can help identify the sources of pain and dysfunction and plan a course of treatment. Swelling around the ulnar styloid and loss of wrist extension secondary to extensor carpi ulnaris subluxation indicate early wrist involvement. Dorsal wrist swelling is commonly present and can be due to radiocarpal synovitis, tenosynovitis, or a combination of the two processes. An inflamed synovial membrane surrounding the radiocarpal joint is usually tender to palpation, but there can be surprisingly little swelling on examination if it is confined only to the dorsal capsule. Swelling that is related to the joint usually does not display movement with passive motion of the digits. Tenosynovitis, however, is typically painless and nontender and moves with tendon excursion as the digits are moved.

Distal radioulnar joint involvement is confirmed with tenderness to palpation, pain, crepitation, limitation of forearm rotation, and prominence of the ulnar head indicating subluxation or dislocation. If the ulnar border of the hand and carpus are in straight alignment with the ulna, it is indicative of radial deviation and carpal supination. As mentioned previously, ulnar drift of the digits at the metacarpophalangeal joints often accompanies this. It is important to examine the function and integrity of the tendons of the digits, primarily the extensor tendons and flexor pollicis longus tendon, to identify any attritional ruptures that may be present.

Examination for provocative signs of carpal tunnel syndrome includes eliciting of Tinel sign over the carpal canal, reproduction or worsening of numbness in the digits with compression over the proximal edge of the canal at the distal wrist crease (Durkan test), and flexion of the wrist (Phalen test). A careful neurologic examination may detect decreased light touch sensibility in the thumb, index, middle, and radial aspects of the ring finger if there is advanced median nerve dysfunction. Consideration should be given

to the possibility of more proximal (cervical neuropathy) causes of symptoms.

If there is significant synovitis of the radiocapitellar joint proximally, there can be posterior interosseous nerve dysfunction as well. This is manifested during the wrist and hand examination as the inability to extend the thumb and digits and, to some extent, the wrist. This finding, however, needs to be differentiated from tendon rupture or subluxation at the level of the metacarpophalangeal joints. Strength testing may be diminished because of pain from synovitis, muscle atrophy, or the inability to contract a muscle secondary to tendon rupture.

Functional Limitations

Rheumatoid patients often have shoulder, elbow, and hand involvement and an abnormal wrist, which leads to significant limitations in activities of daily living. Because the distal radioulnar joint is important in allowing functional forearm rotation and in helping to position the hand in space, advanced synovitis of this joint causing pain and fixed deformity can have a severe impact on a patient's daily functional activity. Functional difficulties that are commonly experienced by these patients include activities of lifting, carrying, and sustained or repetitive grasp. Whereas a loss of pronation may be compensated for by shoulder abduction and internal rotation, supination loss is very difficult to compensate. This can lead to difficulty in opening doors and turning keys. Simple acts such as receiving change during shopping can be compromised by reduced supination. Furthermore, in patients with shoulder involvement, the freedom of compensatory motion at the shoulder can be severely limited, compounding the limitations imposed on the patient's function by limitation of forearm rotation.

Diagnostic Studies

In patients in whom rheumatoid arthritis is suspected clinically, appropriate diagnostic serologic tests may include rheumatoid factor, antinuclear antibody, HLA-B27, sedimentation rate, and anticitrulline antibody assay. These tests are performed in conjunction with a consultation by a rheumatologist or an internist experienced in the care of rheumatoid disease.

Plain radiographs of the wrist that include posterior-anterior, lateral, and oblique views allow thorough examination of the radiocarpal, midcarpal, and distal radioulnar joints. Specifically, a supinated oblique view [12] should be closely inspected for early changes consistent with rheumatoid synovitis. The earliest of these changes are symmetric soft tissue swelling and juxta-articular osteoporosis. Radiographic staging can be performed as well [13] (Table 41.1).

Although most patients already have a diagnosis of rheumatoid arthritis, radiographic examination occasionally detects the earliest signs of the disease by changes in areas of the wrist where there is a concentration of synovitis. These changes include erosions at the base of the ulnar styloid, the sigmoid notch of the distal radius, and the waist of the scaphoid and isolated joint space narrowing of the capitolunate joint seen on the posteroanterior view (Figs. 41.3 and 41.4). Ulnar translocation of the carpus can also be

Table 41.1 Larsen Radiographic Staging of Rheumatoid Arthritis

Larsen Score	Radiographic Status
0	No changes, normal joint
1	Periarticular swelling, osteoporosis, slight narrowing
2	Erosion and mild joint space narrowing
3	Moderate destructive joint space narrowing
4	End-stage destruction, preservation of articular surface
5	Mutilating disease, destruction of normal articular surfaces

FIGURE 41.3 A and B, Radiographs (of the patient in [Figure 41.2](#)) in early rheumatoid disease of the wrist show bone erosions in areas of synovitis, such as around the ulnar styloid and distal radioulnar joint. There are also early erosive changes in the scapholunate articulation. The soft tissue swelling and deformity around the distal ulna are easily appreciated. These radiographs represent Larsen stage 2 disease.

FIGURE 41.4 A, As the disease advances, cystic changes in the radioscaphoid articulation, reduction in joint space, and osteophyte formation are clearly seen in this radiograph of stage 3 disease. B, Radiographic appearance in stage 3 of persistent synovitis around the ulnar head and distal radioulnar joint, which leads to destruction of the ulnar head and osteophyte formation, both of which can contribute to extensor tendon attrition and rupture. There is ulnar translocation of the carpus best appreciated by the ulnar displacement of the lunate.

seen on this view. The lateral radiograph can show small bone spikes protruding palmarly, usually from the scaphoid. Late radiographic changes include pancompartmental loss of joint spaces and large subchondral erosions [14] ([Fig. 41.5](#)). Although radiographic findings may not always correlate well with clinical findings, the information gained from plain radiographs can be important in influencing which procedures will be of most benefit in patients with poor medical disease control. Significant joint subluxation,

FIGURE 41.5 A and B, In advanced disease (stage 4), there is complete loss of joint space affecting the entire wrist, profuse osteophyte formation best appreciated in the lateral view, and deformation and dorsal dislocation of the ulnar head.

bone loss, relative ulnar length, and ulnar translocation can help determine which procedure best serves a patient.

Advanced imaging techniques, such as magnetic resonance imaging and computed tomography, are not usually helpful in evaluation or planning for surgery. Electrodiagnostic studies are recommended if neurologic symptoms are present.

Differential Diagnosis

Post-traumatic arthritis
Chronic scapholunate advanced collapse
Septic arthritis
Septic tenosynovitis
Wrist instability
Carpal tunnel syndrome
Gout

Treatment

Initial

The monitored use of disease-modifying agents has dramatically improved control of the disease, especially with early, aggressive treatment. The medical treatment consists of three categories of drugs: nonsteroidal anti-inflammatory agents; corticosteroids; and disease-modifying drugs, both nonbiologic (i.e., methotrexate) and biologic (i.e., tumor necrosis factor inhibitors) [4]. The details of medical treatment are beyond the scope of this chapter.

Management of local disease depends on several factors, such as severity of disease, functional limitations, pain, and cosmetic deformity. The patient's education, nutrition, and psychological health should be maximized.

Acutely painful, inflamed wrists are best managed with rest and immobilization and oral anti-inflammatory agents. Splints available over-the-counter may be ill-suited for this population of patients because the material cannot mold to altered anatomic contours. In such cases, a custom-made, forearm-based, volar resting splint that holds the wrist in the neutral position will provide support and comfort and is likely to be worn with greater compliance. Splints serve to stabilize joints that are subjected to subluxation forces and to improve grip when it is impaired by pain. However, splinting should be treated as a comfort measure and is not effective for preventing deformity as a result of progression of the disease [15].

Rehabilitation

Occupational therapy can provide potential pain control measures, activity modification education, custom splinting (see Initial Treatment), and exercises for range of motion tendon gliding and strengthening. A home exercise program can be developed to improve function and strength if the disease is also under adequate medical control [15].

In patients affected with local tenosynovitis of the extensor aspect and unwilling to have an injection, a trial of iontophoresis may prove beneficial. In patients with large amounts of subcutaneous adipose tissue, iontophoresis may be of limited efficacy in joints or periarticular structures. Studies on the effects of hot and cold in patients with rheumatoid arthritis show benefits in pain, joint stiffness, and strength but do not prove the superiority of one modality over the other [16]. Paraffin baths and moist heat packs are used to improve joint motion and pain, allowing increased activity tolerance. The results with paraffin baths are superior when they are combined with exercise programs [17]. Hydrotherapy can be an adjunct to many treatment programs, primarily for the purpose of decreasing muscle

tension and reducing pain. Physical therapy particularly focusing on shoulder and elbow range of motion to position the hand in space may be of benefit if multiple joints are affected and symptomatic. Improvement of shoulder and elbow function is important because it is difficult to position a hand in space with a painful, stiff joint proximal to it.

Potentially the most critical role of therapy is in the postoperative period. It is then that patients particularly require monitored splinting, improvement in range of motion and strength, and edema control.

Procedures

Intra-articular cortisone injections are effective in alleviating wrist pain due to synovitis. Typically, all injections around the wrist should be done by aseptic technique with a 25-gauge, 1½-inch needle and a mixture of a steroid preparation, which is injected along with 1% lidocaine. The radiocarpal joint can be injected from the dorsal aspect approximately 1 cm distal to Lister tubercle, with the needle angled proximally about 10 degrees to account for the slight volar tilt of the distal radius articular surface. This is done with the wrist in the neutral position. Gentle longitudinal traction by an assistant can help widen the joint space, which may be reduced on account of the disease.

An alternative radiocarpal injection site is the ulnar wrist, just dorsal or volar to the easily palpable extensor carpi ulnaris tendon at the level of the ulnar styloid process. The needle must be angled proximally by 20 to 30 degrees to enter the space between the ulnar carpus and the head of the ulna. It is important to ascertain that the injectate flows freely. Any resistance indicates a need to reposition the needle appropriately. Alternatively, the injection may be performed with imaging guidance, such as a mini image intensifier or ultrasound, if it is available in the office.

If a midcarpal injection is required, this is done through the dorsal aspect, under fluoroscopic guidance, with injection into the space at the center of the lunate-triquetrum-hamate-capitate region.

Injections into the carpal tunnel are usually performed at the level of the distal wrist crease with the needle introduced just ulnar to the palmaris longus, which in most patients is just palmar to the median nerve and therefore protects it at this level. In patients who do not display clinical evidence of a palmaris longus, we do not recommend carpal tunnel injections. For treatment of associated carpal tunnel syndrome, patients should be issued a wrist splint primarily for nighttime use. Steroid injection into the carpal canal is an option, but the risks of possible attritional tendon rupture need to

be discussed with the patient. Thorough knowledge of local anatomy is essential before an injection into the carpal tunnel is attempted. More important, alteration of local anatomy (and therefore altered location of the median nerve) must be considered very carefully before a carpal tunnel injection.

Patients must be counseled about the postinjection period. It is not uncommon for patients to experience some increase in local discomfort for 24 to 36 hours after the injection. Use of the splint is recommended during this time, and icing of the area may also be of benefit. In our experience, most steroid injections take a few days to have a therapeutic effect. As is the case with any joint, because of the deleterious effect that corticosteroids can have on articular cartilage by transient inhibition of chondrocyte synthesis, repeated injections should be minimized if there is no radiographic sign of advanced cartilage wear, but there is no specific maximum number of injections. On the other hand, in advanced disease, when joint surgery is inevitable, there is no contraindication to repeated injections that have proved beneficial to a patient.

Surgery

The indications for operative treatment of the rheumatoid wrist include one or more of the following: disabling pain and chronic synovitis not relieved by a minimum of 4 to 6 months of adequate medical and nonoperative measures; deformity and instability that limit hand function; tendon rupture; and nerve compression. Deformity alone is rarely an indication for surgery. It is not uncommon to see patients with significant deformities demonstrate excellent function with the use of compensatory maneuvers in the absence of pain. Corrective surgery in these patients is ill-advised.

Surgical procedures can be divided into those involving bone and those involving soft tissue (Table 41.2) [18]. On occasion, a bone procedure will be combined with a soft tissue procedure in the same setting. Synovectomy involves the removal of the inflamed, thickened joint lining from the radiocarpal and distal radioulnar joints and is best performed for the painful joint that demonstrates little or no radiographic evidence of joint destruction. Tenosynovectomy involves débridement of the tissue around involved tendons in the hope of avoiding future attritional tendon ruptures. Patients best suited for these procedures have relatively good medical disease control, no fixed joint deformity, and minimal radiographic changes. If tendon rupture has already occurred, most commonly over the distal ulna, the procedure of choice is some form of tendon transfer, usually combined with resection of the ulnar head (Darrach procedure) [19].

Table 41.2 Wrightington Classification of Rheumatic Disease

Wrightington Grade	Radiographic Findings	Surgical Therapy
1	Preservation of wrist architecture	Synovectomy
2	Periarticular cysts, osteoporosis Preservation of radioscapoid joint Ulnar translocation, flexion of lunate or scaphoid, or radiolunate joint involvement	Darrach procedure, tendon rebalancing, partial arthrodesis
3	Preservation of radius architecture Intracarpal arthritis, radioscapoid joint arthritis, or volar subluxation of carpus	Arthroplasty versus arthrodesis
4	Loss of radius bone stock	Arthrodesis

Repair is not indicated or possible in most cases because of the poor tissue quality and extensive loss of tendon tissue in the zone of rupture. Depending on the number of tendons ruptured, it is possible to transfer the ruptured distal tendon into a neighboring healthier tendon or to transfer a more distant tendon, such as the extensor indicis proprius or superficial flexor tendon, into the affected tendon. The distal end of a ruptured extensor tendon may also be sutured to its unaffected neighboring extensor in some cases.

Bone procedures include resection arthroplasty, resurfacing arthroplasty, and limited or complete wrist fusions. Resection arthroplasty, such as the Darrach procedure, in which the distal ulna is resected, is beneficial in the setting of distal ulnar impingement on the carpus or for distal radioulnar joint disease. It may also prevent tendon rupture of the extensor tendons on the dorsum of the ulnar head. However, it may further ulnar translocation of the carpus and therefore should be combined with a radiolunate arthrodesis in patients with weak ligamentous support where this is a concern (see later). An alternative treatment for debilitating distal radioulnar joint pain is the Sauvé-Kapandji procedure, in which the distal ulna is fused to the distal radius along with a distal ulnar osteotomy. This osteotomy is essentially a resection of a small segment of bone proximal to the fused distal radioulnar joint to construct a “false joint,” or pseudarthrosis, through which the patient may be able to rotate the forearm. Excellent pain relief has been demonstrated in rheumatoid patients with this procedure [20,21]. Although this procedure is better at preventing ulnar translocation, nonunion of the arthrodesis site is an issue, particularly in rheumatoid arthritis patients with poor bone stock.

To address the radiocarpal joint, two options exist: wrist resurfacing arthroplasty or fusion. The arthroplasty requires the resection of a portion of the distal radius and carpus and insertion of an implant usually made of a metallic component with a polyethylene spacer. It is generally restricted to patients with low functional demands who have bilateral rheumatoid wrist disease and require some motion in one wrist if the other is fused. It is most effective in patients who have good bone stock, relatively good alignment, and intact extensor tendons. The benefits of the arthroplasty include maintenance of range of motion and pain relief. Although some studies show promising results with wrist arthroplasty [22–26], other long-term studies show loosening in half to two thirds of the population [27,28], with removal in 25% to 40%.

Fusion, or arthrodesis, procedures to eliminate pain due to significantly degenerative joints are well described [29–34]. However, depending on the nature of the fusion, these lead to a partial or complete loss of wrist motion. Limited fusions are described of the radiolunate joint (Chamay arthrodesis) or the radioscapulohumeral joint. The potential benefit of limited fusions is some sparing of wrist motion, which can occur through the articulations that remain unfused, and this sparing of some motion can be critical to overall function in this group of patients. In each of these procedures, the midcarpal joint must be well preserved.

Total wrist fusion is a reliable, safe, and well-established procedure for relieving pain and providing a stable wrist that improves hand function but without range of motion of the radiocarpal joint [29,30,32]. Success rates of 65% to 85% have been shown in terms of eliminating or significantly improving wrist pain [32]. For advanced wrist rheumatoid disease, it

has become the most common bone procedure. Fusion can be accomplished either with a contoured dorsal plate fixed to the wrist by screws or with one or more large intraosseous pins placed across the wrist (Fig. 41.6). The intraosseous pins

FIGURE 41.6 A and B, Radiographs depicting a total wrist arthrodesis with use of a contoured plate and screws. Note that the distal end of the ulna has also been excised (Darrach procedure). The polyarthritic nature of the disease process is emphasized by the metacarpophalangeal joint arthroplasties in the fingers and a metacarpophalangeal arthrodesis of the thumb.

are usually placed through the second or third metacarpal or through both, across the wrist into the medullary canal of the radius. Ideally, the wrist is fused in slight extension to allow improved grip strength. However, if both wrists are to be fused, one may consider fusing one in slight flexion and the other in slight extension to allow functional differences [5]. High rates of fusion and a 15% rate of symptomatic hardware removal have been described [31]. Consideration of the quality of the overlying soft tissue is necessary in deciding on a fusion technique, as more soft tissue dissection is necessary for the plate and may result in wound complications.

If significant median nerve compression exists, an extended open carpal tunnel release with flexor tenosynovectomy is typically performed through a palmar incision.

Potential Disease Complications

Rheumatoid arthritis is a chronic, progressive disease that can cause significant upper extremity disability at many locations by stiffness or instability from the shoulder to the hand. If wrist involvement becomes advanced, this contributes to problems with motion, pain, stiffness, and nerve compression. Extensor and flexor tendon rupture is a common scenario in rheumatoid disease and can complicate management. During the course of their disease, most patients with rheumatoid disease will lose some functional capacity, and about half will have disabling disease that requires significant physical dependence on adaptive measures for performance of the activities of daily living. Occupational therapists and social workers play roles in obtaining and using aids and appliances, such as special grips and alterations of household appliances, to maximize the patient's function.

Potential Treatment Complications

Systemic complications from the medical treatment of rheumatoid arthritis with current disease-modifying agents are beyond the scope of this chapter. Analgesics and nonsteroidal anti-inflammatory medications have well-known side effects that can affect the cardiac, gastric, renal, and hepatic systems. Intra-articular corticosteroid injections involve a very small risk of infection as well as cumulative cartilage injury from repeated exposure to steroid.

Surgical complications can result from wound healing problems, infection, neurovascular injury, recurrent synovitis, recurrent tendon rupture, persistent joint instability, and implant loosening or failure. To some extent, meticulous surgical technique and judicious management of medications affecting wound healing and immunity, such as methotrexate and systemic steroids, may reduce the frequency of complications.

encounter fracture with delayed healing,
K—subsequent encounter fracture with
nonunion, S—sequela)

Definition

A compression fracture is caused by forces transmitted along the vertebral body. The ligaments are intact, and compression fractures are usually stable [1] (Fig. 42.1).

Compression fractures in the thoracic vertebrae are commonly seen in osteoporosis with decreased bone mineral density. They may be asymptomatic and diagnosed incidentally on radiography. Such fractures may occur with trivial trauma and are usually stable [2,3]. Pathologic vertebral fractures may occur with metastatic cancer (commonly from lung, breast, or prostate) as well as with other processes affecting vertebrae. Trauma, such as a fall from a height or a motor vehicle accident, can also result in thoracic compression fracture. Considerable force is required to fracture healthy vertebrae, which are resistant to compression. In such cases, the force required to produce a fracture may cause extension of fracture components into the spinal canal with neurologic findings. There may be evidence of additional trauma, such as calcaneal fractures from a fall. Multiple thoracic compression fractures, as seen with osteoporosis, can produce a kyphotic deformity [4–6]. An estimated 1.5 million vertebral compression fractures occur annually in the United States, with 25% of postmenopausal women affected in their lifetime. Estimates indicate that there are 44 million persons with osteoporosis and 34 million with low bone mass in the United States [7]. Existence of vertebral compression fracture increases the risk of future vertebral compression fractures (with 1 fracture, there is a 5-fold increase; with 2 or more fractures, there is a 12-fold increase) [8].

Symptoms

Pain in the thoracic spine over the affected vertebrae is the usual hallmark of the presentation. It may be severe, sharp, exacerbated with movement, and decreased with rest. Severe pain may last 2 to 3 weeks and then decrease during 6 to 8 weeks, but pain may persist for months. Acute fractures in osteoporosis, however, may result in little discomfort or poor localization [9]. In osteoporotic fractures, the mid and lower thoracic vertebrae are typically affected. A good history and physical examination

FIGURE 42.1 Thoracic compression fracture with reduction in anterior vertebral height and wedging of the vertebrae.

are essential as there may be indicators of a more ominous underlying pathologic process [10,11].

Physical Examination

Tenderness with palpation or percussion over the affected region of the thoracic vertebrae is the primary finding on physical examination. Spinal movements also produce pain. Kyphotic deformity, loss of height, and impingement of the lower ribs on the superior iliac crest may be present in the patient who has had multiple prior compression fractures. Neurologic examination below the level of the fracture is recommended to assess for presence of reflex changes, pathologic reflexes such as Babinski sign, and sensory alterations. Sacral segments can be assessed through evaluation of rectal tone, volitional sphincter control, anal wink, and pinprick if there is concern about bowel and bladder function [12]. It is also important to assess the patient's gait for stability. Comorbid neurologic and orthopedic conditions may contribute to gait dysfunction and fall risk [13,14].

Functional Limitations

Functional limitations in a patient with an acute painful thoracic compression fracture can be significant. The patient may experience loss of mobility and independence in activities of daily living and household activities, and there may be an impact on social, avocational, vocational, and psychological functioning. In patients with severe symptoms, hospitalization may be necessary [15].

Diagnostic Testing

Anteroposterior and lateral radiographs of the thoracic spine can confirm the clinical impression of a thoracic compression fracture. On radiographic examination in a thoracic compression fracture, the height of the affected vertebrae is reduced, generally in a wedge-shaped fashion, with anterior height less than posterior vertebral height. In osteoporosis, biconcave deformities can also be noted on spinal radiographs (Fig. 42.2A). A bone scan may help localize (but not necessarily determine the etiology of) processes such as metastatic cancer, occult fracture, and infection. Spinal imaging, such as computed tomography or magnetic resonance imaging, may also elucidate further detail [16] (Fig. 42.2B). Percutaneous needle biopsy of the affected vertebral body can be helpful diagnostically in selected cases. Laboratory tests are obtained as appropriate. These include a complete blood count and sedimentation rate or C-reactive protein level (which are nonspecific but sensitive indicators of an occult infection or inflammatory disease). Serum alkaline phosphatase, serum and urine protein electrophoresis, and other laboratory tests are beneficial when a malignant neoplasm is suspected. Diagnostic testing is directed, as appropriate, on the basis of the entire clinical presentation, including secondary causes of osteoporosis. Bone densitometry can be performed when the patient is improved clinically.

Differential Diagnosis

Thoracic sprain
 Thoracic radiculopathy
 Thoracic disc herniation
 Metastatic malignant disease
 Primary spine malignant neoplasm (uncommon, most frequently multiple myeloma) [17]
 Benign spinal tumors
 Infection, osteomyelitis (rare) [18]
 Inflammatory arthritis
 Musculoskeletal pain, other
 Referred pain (pancreatic cancer, abdominal aortic aneurysm)

Treatment

Initial

Initial treatment consists of activity modification, including limited bed rest. Cushioning with use of a mattress overlay (such as an egg crate) can also be helpful. Pharmacologic agents, including oral analgesics, muscle relaxants, and anti-inflammatory medications, as appropriate to the patient, are helpful. Agents such as tramadol 50mg (one or two every 4 to 6 hours, not exceeding eight per day), acetaminophen 300mg/codeine 30mg (one or two every 4 to 6 hours), and controlled-release oxycodone CR (10mg or 20mg every 12 hours) may be considered. Acetaminophen dose should not exceed 3g/day. Muscle relaxants such as cyclobenzaprine, 10mg three times daily, may be helpful initially with muscle spasm. A variety of nonsteroidal anti-inflammatory drugs, including celecoxib (Celebrex, a cyclooxygenase 2 inhibitor),

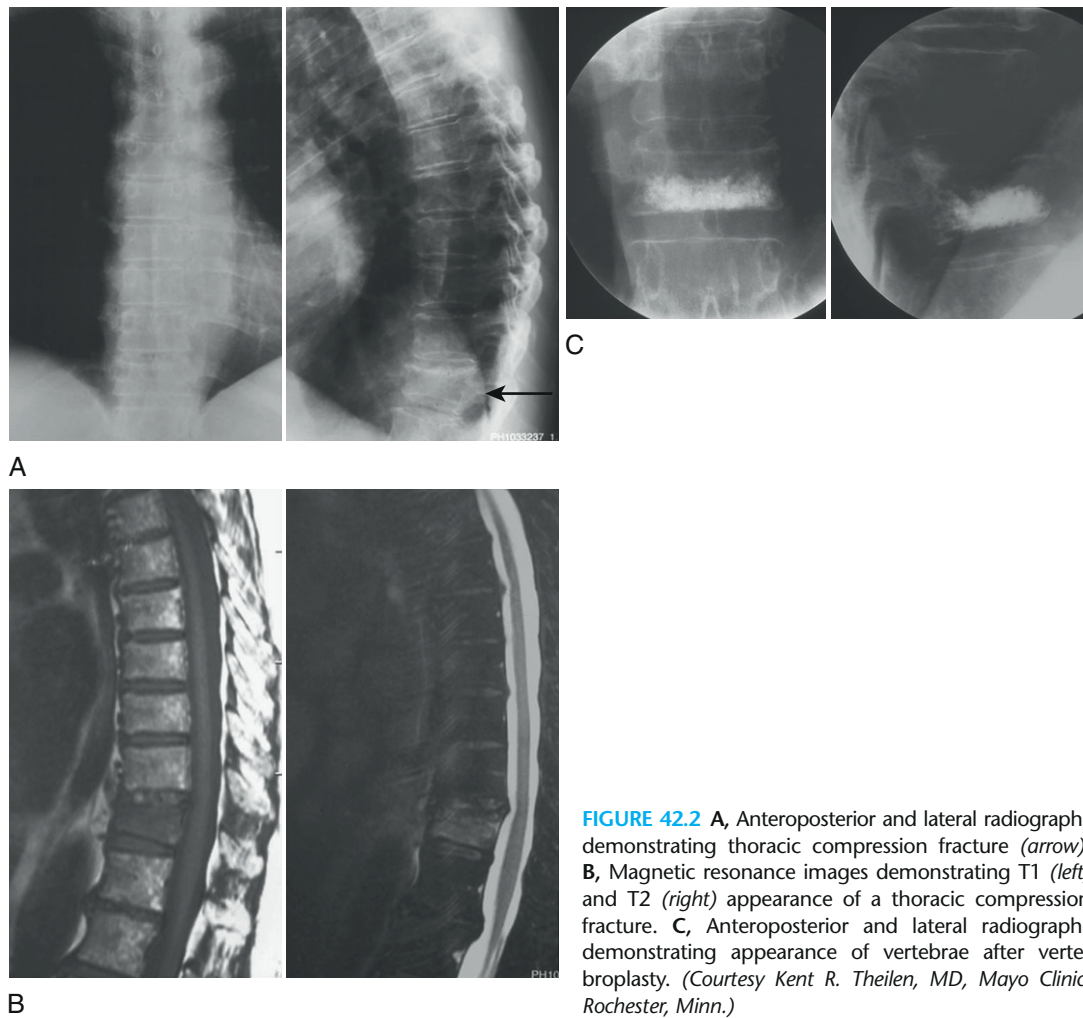

FIGURE 42.2 A, Anteroposterior and lateral radiographs demonstrating thoracic compression fracture (arrow). can be considered, depending on the patient. Calcitonin (one spray daily, alternating nostrils, providing 200IU per spray) has also been used for painful osteoporotic fractures [19]. Stool softeners and laxatives may be necessary to reduce strain with bowel movements and constipation, particularly with narcotic analgesics. Selection of pharmacologic agents must factor in the age, comorbidities, and clinical status of the patient. Avoidance of spinal motion, especially flexion, by appropriate body mechanics (such as log rolling in bed) and spinal bracing is helpful. There are a variety of spinal orthoses that reduce spinal flexion (Fig. 42.3). They must be properly fitted [20,21]. A lumbosacral orthosis may be sufficient for a low thoracic fracture. A thoracolumbosacral orthosis is used frequently (Fig. 42.3A-D). If a greater degree of fracture immobilization is required, an off-the-shelf orthosis (Fig. 42.3E) or a custom-molded body jacket may be fitted by an orthotist. Proper diagnosis and treatment of underlying contributors to the thoracic compression fracture are necessary [22,23]. Most thoracic compression fractures will heal with symptomatic improvement in 4 to 6 weeks [24,25].

Rehabilitation

Physical therapy is helpful to assist with gentle mobilization of the patient by employing proper body mechanics,

optimizing transfer techniques, and training with gait aids (such as a wheeled walker) to reduce biomechanical stresses on the spine and to ensure gait safety [26]. Pain-relieving modalities, such as therapeutic heat or cold, and transcutaneous electrical stimulation may also be employed. Exercise should not increase spinal symptoms and should be implemented at the appropriate juncture. In addition to proper body mechanics and postural training emphasizing spinal extension and avoidance of flexion, spinal extensor muscle strengthening, limb muscle strengthening, stretching to muscle groups (such as the chest, hips, and lower extremity muscles), and deep breathing exercises may also be indicated. Weight-bearing exercises for bone health, balance, and fall prevention are also important [27]. Proper footwear, with cushioning inserts, can also be helpful. Occupational therapy can help the patient with activities of daily living, reinforce proper spinal ergonomics, address equipment needs, and prevent falls. Successful rehabilitation is targeted at increasing the patient's comfort, decreasing deformity, and decreasing resultant disability and is individualized to address specific patient needs [28–30].

Procedures

Invasive procedures are generally not necessary. Percutaneous vertebroplasty or kyphoplasty with use of polymethyl

FIGURE 42.3 A, Cruciform anterior spinal hyperextension brace (to limit flexion). B, Three-point sagittal hyperextension brace (to limit flexion). C, Thoracolumbosacral orthosis, anterior view. methacrylate may be helpful to reduce fracture pain, to reinforce thoracic vertebral strength, and to improve function; with kyphoplasty, some potential restoration of vertebral height has been reported [26,31] (Fig. 42.2C). Patients with imaging evidence of an acute or a subacute thoracic fracture who have correlating pain, who fail to improve with conservative management, and who are without contraindications may be candidates for such interventional procedures [32,33]. In two randomized controlled trials, no beneficial effect was noted in vertebroplasty versus sham [32,34].

Surgery

Surgery is rarely necessary. Surgical stabilization can be considered in patients with continued severe pain after compression fracture as a result of nonunion of the fracture, in patients with spinal instability, or if neurologic complications occur. Referral to a spine surgeon is recommended in these cases for further assessment [35].

Potential Disease Complications

Neurologic complications, including nerve or spinal cord compromise, as well as orthopedic complications with continued pain, nonunion, and instability can occur. Underlying primary disease, for example, metastatic thoracic compression, needs to be addressed. Patients with severe kyphosis may experience cardiopulmonary dysfunction. Severe kyphosis may also result in rib impingement on the iliac bones, producing further symptoms. Severe pain accompanying a fracture may further limit deep breathing and increase the risk of pulmonary complications, such as pneumonia. Progressive spinal deformity may produce secondary pain generators. The patient may have progressive levels of dependency as a result.

Potential Treatment Complications

Side effects with medications, particularly nonsteroidal anti-inflammatory drugs as well as narcotic medications, can occur. It is important to select medications appropriate for individual patients. There may be difficulty with the use of spinal orthotics, such as intolerance in patients with gastroesophageal reflux disease. Kyphotic patients frequently do not tolerate orthoses and fitting is a problem. Complications of vertebroplasty or kyphoplasty can include infection, bleeding, fracture (in the treated or adjacent vertebrae), and systemic issues such as embolism. Cement leaks into surrounding tissues with spinal cord, spinal nerve, or vascular compression can occur [36]. Surgery can result in many complications, not only from general anesthesia risks but also from infection, bleeding, or thromboembolism. Poor mechanical strength of bone, as in osteoporosis with paucity of dense lamellar and cortical bone, may result in suboptimal surgical outcome.

Acknowledgments

The author thanks Dr. Kent Thielen for use of the case study; Sara Harstad for orthotic modeling; and Pamela Harders for secretarial support.

724.4 Thoracic or lumbosacral neuritis or
radiculitis, unspecified

ICD-10 Code

M54.14 Radiculopathy, thoracic region

Definition

Thoracic radiculopathy is a painful syndrome caused by mechanical compression, chemical irritation, or metabolic abnormalities of the thoracic spinal nerve root. Thoracic disc herniation accounts for less than 5% of all disc protrusions [1,2]. It accounts for less than 2% of all spinal disc surgeries and 0.15% to 4% of all symptomatic spinal disc herniations [3]. The majority of thoracic disc herniations (35%) occur between the levels of T8 and T12, with a peak (20%) at T11-12. Most patients (90%) present clinically between the fourth and seventh decades of life; 33% present between the ages of 40 and 49 years. Approximately 33% of thoracic disc protrusions are lateral, preferentially encroaching on the spinal nerve root. The remainder are central or central lateral, resulting primarily in various degrees of spinal cord compression. Synovial cysts, although rare in the thoracic spine (0.06% of patients requiring decompressive surgery), may also be responsible for foraminal encroachment. These tend to be more common at the lower thoracic levels [4].

Natural degenerative forces and trauma are generally thought to be the most important factors in the etiology of mechanical thoracic radiculopathy. Foraminal stenosis from bone encroachment may also cause compression of the

exiting nerve root and radicular symptoms. Perhaps one of the most common metabolic causes of thoracic radiculopathy is diabetes, often resulting in multilevel disease [4]. This may occur at any age but often appears with other neuropathic symptoms due to injury to the blood supply to the nerve root. Finally, another etiology that should be considered a possible cause of thoracic radiculopathy is neoplastic compression. Primary spine tumors are rare, although the spine is a frequent metastasis site (4%-15%) of primary solid tumors, such as breast, lung, and prostate cancer [5]. Regarding spine metastasis, the thoracic spine is the most commonly affected (70%), followed by lumbar (20%) and cervical (10%) [6].

Symptoms

Most patients (67%) present with complaints of “band-like” chest pain (Fig. 43.1). The second most common symptom (16%) is lower extremity pain [7]. Injury to nerve roots T2-3 may be manifested as axillary or midscapular pain. Injury to nerve roots T7-12 may be manifested as abdominal pain [8]. Unlike thoracic radiculopathy, spinal cord compression produces upper motor neuron signs and symptoms consistent with myelopathy. Therefore examiners should pay close attention to the presence of motor impairment, hyperreflexia and spasticity, sensory impairment, and bowel and bladder dysfunction. The last may be caused by T11-12 lesions damaging the conus medullaris or cauda equina [9].

Thus, in thoracic radiculopathy, pain—localized, axial, or radicular—is the primary complaint in 76% of patients. It is also important to include in the history any trauma (present in 37% of patients) [10] or risk factors for non-neurologic causes of chest wall or abdominal pain. Thoracic compression fractures that may mimic the symptoms of thoracic radiculopathy may be seen in young people with acute trauma, particularly falls, regardless of whether they land on their feet. In older people (particularly women with a history of osteopenia or osteoporosis) or in individuals who have prolonged history of steroid use, a compression fracture should be considered. Because thoracic radiculopathy is not common, it is important in nontraumatic cases to be suspicious of more serious pathologic processes, such as malignant disease. Therefore a history of weight loss, decreased appetite, and previous malignant disease should be elicited.

FIGURE 43.1 Typical pain pattern in a thoracic radiculopathy.

Physical Examination

The physical examination may show only limitations of range of motion—particularly trunk rotation, flexion, and extension—generally due to pain. In traumatic cases, location of ecchymosis or abrasions should be noted. Range of motion testing should not be done repeatedly if an acute spinal fracture is suspected. Careful palpation for tenderness over the thoracic spinous and transverse processes as well as over the ribs and intercostal spaces is critical in localizing the involved level. Pain with percussion over the vertebral bodies should alert the clinician to the possibility of a vertebral fracture.

On the other hand, uncommon symptoms in the lower limbs, such as pain, reflex changes, spasticity, and weakness, can be a result of spinal cord compression by thoracic disc herniation [11], although this phenomenon is seldom observed.

Physical examination in diagnosis of thoracic radiculopathy has a modest accuracy and reliability because there is difficulty in testing strength of possibly affected muscles (such as paraspinal, intercostal, and abdominal muscles) isolatedly [12], although it is crucial for ruling out other possible causes of pain or neurologic abnormalities. In addition, sensation may be abnormal in a dermatomal pattern. This will direct the examiner to more closely evaluate the involved level. Any abnormalities of the spine should be noted, including scoliosis, which is best detected when the patient flexes forward. A thorough examination of the cardiopulmonary system, abdominal organs, and skin should be

performed, particularly in individuals who have sustained trauma or relevant comorbidities.

Functional Limitations

The pain produced by thoracic radiculopathy often limits an individual's movement and activity. Patients may be limited in activities such as dressing and bathing and other activities that include trunk movements, such as putting on shoes. Work activities may be restricted, such as lifting, climbing, and stooping. Even sedentary workers may be so uncomfortable that they are not able to perform their jobs. Anorexia may result from pain in the abdominal region.

Diagnostic Studies

Because of the low incidence of thoracic radiculopathy and the possibility of serious disease (e.g., tumor), the clinician should have a low threshold for ordering imaging studies in patients with persistent (more than 2 to 4 weeks) thoracic pain of unknown origin. Magnetic resonance imaging remains the imaging study of choice to evaluate the soft tissue structures of the thoracic spine. Computed tomography and computed tomographic myelography are alternatives if magnetic resonance imaging cannot be obtained.

The electromyographic evaluation of thoracic radiculopathy can be challenging because of the limited techniques available and the lack of easily accessible muscles representing a myotomal nerve root distribution. The muscles most commonly tested are the paraspinals, intercostals, and abdominals. The clinician must investigate multiple levels of the thoracic spine to best localize the lesion. Techniques for intercostal somatosensory evoked potentials have also been shown to isolate individual nerve root levels [8].

In patients who have sustained trauma, plain radiographs are advised to rule out fractures and spinal instability.

Differential Diagnosis

SPINAL DIAGNOSES

- Compression fracture
- Malignant neoplasm (primary or metastatic)
- Pott disease (tuberculosis of the spine)

EXTRASPINAL DIAGNOSES

- Intercostal neuralgia
- Postherpetic neuralgia
- Myofascial trigger point
- Enthesopathy (ligament or tendon)
- Costovertebral joint dysfunction
- Costotransverse ligament sprain
- Rib fracture
- Angina
- Myocardial infarction
- Aortic aneurysm
- Cholecystitis
- Pyelonephritis
- Peptic ulcer disease
- Esophageal disorders
- Mastalgia
- Pleuritis
- Pulmonary embolism
- Adiposis dolorosa

Treatment

Initial

Pain control is important early in the disease course. Patients should be advised to avoid activities that cause increased pain and to avoid heavy lifting. Nonsteroidal anti-inflammatory drugs are often the first line of treatment and help control pain and inflammation. Oral steroids can be powerful anti-inflammatory medications and are typically used in the acute stages. This is generally done by starting at a moderate to high dose and tapering during several days. For example, a methylprednisolone (Medrol) dose pack is a prepackaged prescription that contains 21 pills. Each pill is 4 mg of Solu-Medrol. The pills are taken during the course of 6 days. On the first day, six tablets are taken, and then the dose is decreased by one pill each day. Both non-narcotic and narcotic analgesics may be used to control pain. In subacute or chronic cases, other medications may be tried, such as tricyclic antidepressants and anticonvulsants (e.g., gabapentin and carbamazepine), which have been effective in treating symptoms of neuropathic origin [13,14]. Moist heat or ice can be used, as tolerated, for pain. Transcutaneous electrical nerve stimulation units may also help with pain [15].

Rehabilitation

Physical therapy can be used initially to assist with pain control. Modalities such as ultrasound and electrical stimulation may reduce pain and improve mobility [16]. Physical therapy can then progress with spine stabilization exercises, back and abdominal strengthening [17], and a trial of mechanical spine traction [18]. Some patients may benefit from a thoracolumbar brace to reduce segmental spine movement [19], although it should be carefully used because of possible postural muscle weakness that can result from its long-term use. Patients with significant spinal instability documented by imaging studies should be referred to a spine surgeon.

In addition, physical therapy should address postural retraining, particularly for individuals with habitually poor posture. Work sites can be evaluated, if indicated. All sedentary workers should be counseled on proper seating, including use of a well-fitting adjustable chair with a lumbar support. More active workers should be advised on appropriate lifting techniques and avoidance of unnecessary trunk rotation.

Finally, physical therapy can focus on improving biomechanical factors that may play a role in abnormal loads on the thoracic spine. These include flexibility exercises for tight hamstring muscles and orthotics for pes planus (flat feet).

Procedures

Transforaminal injections can have both diagnostic and therapeutic purposes [20]. They have been shown to significantly reduce radiating pain [21]. This is done under fluoroscopic guidance to minimize risk of injury to the lung and to ensure the accuracy of the level of injection.

Surgery

Thoracoscopic microsurgical excision of herniated thoracic discs has been shown to have excellent outcomes with less

surgical time, less blood loss, fewer postoperative complications, and shorter hospitalizations than more traditional and invasive surgical approaches [22,23]. Traditionally, mechanical causes of thoracic radiculopathy have been treated with posterior laminectomy, lateral costotransversectomy, or anterior discectomy by a transthoracic approach. In a cohort study with 167 patients who underwent thoracoscopic discectomy, 79% reported a good or excellent outcome regarding pain improvement, and 80% reported good or excellent outcome for motor function [24].

Potential Disease Complications

If it is left untreated, thoracic radiculopathy can result in chronic pain and its associated comorbidities. Progressive thoracic spinal cord compression, if unrecognized, can lead to paraparesis, neurogenic bowel and bladder, and spasticity.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Care should be taken with use of steroids in diabetic patients because they may elevate blood glucose levels. In patients with uncontrolled diabetes who present with thoracic radiculopathy, glucose control should be attempted, although extremely elevated serum glucose levels have not been proved to cause the diabetic form of thoracic radiculopathy. Because of the risk of gastric ulceration, steroids are not typically used simultaneously with nonsteroidal anti-inflammatory drugs. Rarely, short-term oral steroid use may produce avascular necrosis of the hip. Tricyclic antidepressants may cause dry mouth and urinary retention. Along with anticonvulsants, they may also cause sedation. On occasion, physical therapy may exacerbate symptoms. The risks of invasive pain procedures and surgery, including bleeding, infection, and further neurologic compromise, are well documented.

Thoracic Sprain or Strain

Darren Rosenberg, DO

Daniel C. Pimentel, MD

Synonyms

Thoracic sprain
Pulled upper back
Benign thoracic pain

ICD-9 Codes

721.2 Thoracic spondylosis, aggravated
724.1 Thoracalgia (thoracic–mid back pain)
847.1 Sprains and strains of other unspecified parts of back (thoracic)
847.2 Thoracic strain

ICD-10 Codes

M47.814 Spondylosis, thoracic region
M54.6 Pain in thoracic spine
S23.3 Sprain of the thoracic spine
S39.012 Strain of muscle, fascia and tendon of lower back

Definition

Thoracic strain or sprain refers to the acute or subacute onset of pain in the region of the thoracic spine due to soft tissue injury, including muscles, ligaments, tendons, and fascia, of an otherwise normal back. Sprain relates to injury in ligament fibers without total rupture, whereas strain is an overstretching or overexertion of some part of the musculature [1]. Because the thoracic cage is unified by the overlying fascia, thoracic sprain or strain can translate into pain throughout the thoracic spine.

Epidemiology

Although the scientific literature on musculoskeletal pain in the cervical and lumbar spine is abundant, similar

information about the thoracic region is sparse because of its lower prevalence [2]. The lifetime prevalence in the general population of having a musculoskeletal complaint in the thoracic spine is 17% in contrast to 57% in the low back and 40% in the neck [3]. Therefore observation and characterization of such lesions are minimal, subsequently limiting the potential to improve treatment methods for thoracic sprain and strain disorders. Moreover, pain felt in the thoracic spine is often referred from the cervical spine, mistakenly giving the impression that the incidence is higher [4].

Thoracic strain or sprain may be the indirect result of disc lesions, which have been reported to be evenly distributed in incidence between the sexes and are most common in patients from the fourth to sixth decades of life [5]. Muscles adjacent to the injured disc tend to become tight in response to the local inflammatory process, which may jeopardize the local muscle equilibrium, possibly leading to ligament strains and muscle sprains in the thoracic region. Other structures that may lead to strain or sprain in the mid back due to the same inflammatory rationale are the thoracic facet joints and the nerve roots [6].

As with most nonspecific mechanical disorders of the cervical and lumbar regions, the natural history of the majority of patients with nonspecific thoracic strain or sprain is resolution within 1 to 6 months [7].

Mechanisms

The thoracic spine is considered to be the least mobile area of the vertebral column secondary to the length of the transverse processes, the presence of costovertebral joints, the decrease in disc height compared with the lumbar spine, and the presence of the rib cage. Movements that occur in the thoracic spine include rotation with flexion or extension.

Thoracic sprain and strain injuries can occur in all age groups, but there is an increased prevalence among patients of working age [8]. Intrinsic mechanisms include bone disease as well as alteration of normal spine or upper extremity biomechanics. This includes cervical or thoracic deformity from neuromuscular or spinal disease as well as shoulder or scapular dysfunction. The most common intrinsic cause of thoracic strain, however, is poor posture or excessive sitting. Poor posture may be related to development of Scheuermann disease in the young and osteoporosis in the elderly that leads to kyphosis and compression deformities seen in those patients.

Poor posture is often manifested as excessive protraction or drooping of the neck and shoulders as well as decreased lumbar lordosis or “flat back.” With the classic “slouched position” encountered in children and adolescents and often carried on through adulthood, there is excessive flexion of the thoracic spine with a decrease in rotation and extension.

Postural alterations promote increased thoracic kyphosis, resulting in the “flexed posture.” Excessive flexion results in excessive strain on the “core,” including the small intrinsic muscles of the spine, the long paraspinal muscles, and the abdominal and rib cage muscles. Excessive flexion can increase the risk of rib stress fractures as well as costovertebral joint irritation. This can cause referral of pain to the chest wall with subsequent development of trigger points in the erector spinae, levator scapulae, rhomboids, trapezius, and latissimus dorsi. Poor motion in extension and rotation can place an increased load on nearby structures, such as the lumbar or cervical spine and shoulders.

Extrinsic or environmental mechanisms include repetitive strain, trauma, and obesity. Risk factors include occupational and recreational activities characterized by repetitive motions, such as lifting, twisting, and bending. Occupations requiring manual labor or extended periods in a sitting position are predisposed to a higher incidence of such disorders [9]. Traumatic causes include falls, violence, and accidents leading to vertebral fractures, chest wall contusions, or flail chest.

Symptoms

Patients typically report pain in the mid back, which may be related to upper extremity or neck movements. Symptoms may be exacerbated by deep breathing, coughing, rotation of the thoracic spine, or prolonged standing or sitting. The pain can be generalized in the mid back area or focal. If it is focal, it is usually described as a “knot,” which is deep and aching. It may radiate to the anterior chest wall, abdomen, upper limb, cervical spine, or lumbosacral spine and may be accentuated with movement of the upper extremity or neck. As described by McKenzie [4], the location of pain in mechanical disorders of the thoracic spine is either central (symmetric) or unilateral (asymmetric).

Other symptoms include muscle spasm, tightness, and stiffness as well as pain or decreased range of motion in the mid back, low back, neck, or shoulder.

Physical Examination

The essential finding in the physical examination of thoracic sprain or strain is thoracic muscle spasm with normal neurologic examination findings. Pain may be exacerbated when the patient lifts the arms overhead, extends backward, or rotates. Rib motion may be restricted and may be assessed by examining excursion of the chest wall. This is accomplished by laying hands on the upper and lower chest wall and looking for symmetry and rhythm of movement. The upper ribs usually move in a bucket-handle motion, whereas the lower ribs move in a pump-handle motion. Restriction of specific ribs can be assessed by examining individual rib movements with respiration.

The position of comfort is usually flexion, but this is the position that should be avoided. Sensation and reflex examination findings should be normal. A finding of lower

extremity weakness or neurologic deficit on physical examination suggests an alternative diagnosis and may warrant further investigation [10].

As the thoracic cage and spine are the anchors for the upper limbs, the thoracic spine influences and is influenced by active and resisted movement of the extremities, cranium, and lumbar and cervical spine [11]. Therefore, a careful spinal and shoulder examination is essential to rule out restrictive movements, obvious deformity, soft tissue asymmetry, and skin changes (that may be seen in infection or tumor). Detailed examination of other organ systems is important because thoracic pain can be referred.

Examination includes static and dynamic assessment of posture. The patient should be observed in relaxed stance with the shirt removed. Viewing is from the posterior, lateral, and anterior perspectives, and deviations from an ideal posture are noted [11]. With dynamic assessment, it is important to provoke the patient's symptoms by moving and stressing the structures from which pain is thought to originate.

In addition, the presence of deformities and the site of pain and tenderness are noted. Pain is often felt between the scapulae, around the lower border of the scapula, and centrally in the area between T1 and T7. Much of the pain felt in the thoracic area, however, has been shown to originate in the cervical spine. Pain in the region above an imaginary line drawn between the inferior borders of the scapulae is most likely secondary to the cervical region, mainly lower cervical facet joints [12].

Functional Limitations

Functional limitations include difficulty with bending, lifting, and overhead activities, such as throwing and reaching. These limitations affect both active and sedentary workers. Activities of daily living, such as upper extremity bathing and dressing, might be affected. General mobility may be impaired. As most sports-related or leisure activities involve use of the upper extremity, extension, or rotation of the thorax, athletic participation and functional capacity may be limited as well.

Diagnostic Studies

Thoracic sprain and strain injuries are typically diagnosed on the basis of the history and physical examination. No tests are usually necessary during the first 4 weeks of symptoms if the injury is nontraumatic. If there is suspicion of tumor (night pain, constitutional symptoms), infection (fever, chills, malaise), or fracture (focal tenderness with history of trauma or fall), earlier and more complete investigation is warranted.

Plain films are indicated as an initial image diagnostic approach if the injury is associated with recent trauma or malignant disease. Magnetic resonance imaging is the study of choice in considering thoracic malignant neoplasia and osteoporotic compression fracture or when the patient has unilateral localized thoracic pain with sensory-motor deficits to rule out a thoracic disc herniation with consequent radiculopathy [13]. A computed tomographic scan or triple-phase bone scan can identify bone abnormalities if magnetic resonance imaging is contraindicated. Magnetic resonance

imaging, however, can detect abnormalities unrelated to the patient's symptoms because many people who do not have pain have abnormal imaging findings [14]. This fact emphasizes the importance of a meticulous clinical evaluation of patients with thoracic pain.

Differential Diagnosis

SPINAL DIAGNOSES

Thoracic radiculopathy
Facet joint arthropathy
Structural rib dysfunction
Spinal stenosis
Scheuermann disease
Ankylosing spondylosis
Discitis
Vertebral fracture (trauma, insufficiency, pathologic)
Scoliosis or kyphosis

EXTRASPINAL DIAGNOSES

Peptic ulcer disease
Pancreatitis
Cholecystitis
Nephrolithiasis
Shingles

Treatment

Initial

The initial treatment of a thoracic sprain or strain injury generally involves the use of cold packs to decrease pain and edema during the first 48 hours after the injury. Thereafter, the application of moist heat to reduce pain and muscle spasm is indicated. Bed rest for up to 48 hours may be beneficial, but prolonged bed rest is discouraged because it can lead to muscle weakness. Relative rest by avoidance of activities that exacerbate pain is preferable to complete bed rest. Temporary use of a rib binder or elastic wrap may reduce pain as well as increase activity tolerance and mobility. A short course of nonsteroidal anti-inflammatory drugs, acetaminophen, muscle relaxants, or topical anesthetics such as Lidoderm patches may be beneficial. Narcotics are generally not necessary.

Rehabilitation

Most acute thoracic sprain or strain injuries will heal spontaneously with rest and physical modalities used at home, such as ice, heating pad, and massage. Body mechanics and postural training are important aspects of the rehabilitation program for thoracic sprain or strain [15,16]. A focus on correct posture at work, at leisure, and while driving is important. In the car, patients can use a lumbar roll to promote proper posture; at work, patients are advised to sit upright at the computer in an adjustable, comfortable chair with an adequate monitor adjustment. The monitor should be adjusted to be aligned with the keyboard and in a height that aligns the first row of text with eye level. Finally, the correct depth should be achieved in a way that the user does not need to lean forward to comfortably read [17]. Other

workplace modifications include forearm seat rests to support the arms, foot rests, and the use of a telephone earpiece or headset to prevent neck and upper thoracic strain.

For patients with abnormally flexed or slouched posture, household modifications can be made that might help encourage extension and subsequently decrease pain. These include pillows or lumbar rolls on chairs and replacement of sagging mattresses with firm bedding. Also, use of paper plates and lightweight cookware in the kitchen and reassignment of objects in overhead cabinets to areas that are more accessible can help if lifting or reaching is painful.

If pain persists beyond a couple of weeks, physical therapy may be indicated. In general, physical therapy will apply movements that centralize, reduce, or diminish the patient's symptoms while discouraging movements that peripheralize or increase the patient's symptoms [4]. In most cases, an active approach that encourages stretching and strengthening exercises is preferred to a more passive approach. To correct sitting posture, patients are advised to continue to use the lumbar roll in all sitting environments. To correct standing posture, patients are shown how to normalize lumbar curvature and to move the lower part of the spine backward while at the same time moving the upper spine forward, raising the chest and retracting the head and neck. To correct lying posture, patients should use a firm mattress as previously indicated. In the case of patients who experience more pain in the thoracic spine when lying in bed, this advice often leads to worsening of the symptoms rather than a resolution. In these patients, advice should be given to deliberately sag the mattress by placing pillows under each end of the mattress so that it becomes dishd. In this manner, the thoracic kyphosis is not forced into the extended range in lying supine, and the removal of this stress allows a comfortable night's sleep. Long-term goals, however, still include improvement in extension range of motion [4].

After a formal physical therapy program is completed, a home exercise or gym regimen is essential and should be prescribed and individualized for all patients to maintain gains made during physical therapy. Exercises at home are aimed at improvement in flexibility of the thoracic spine and may include extension in lying, standing, and sitting performed six to eight times throughout the day. In addition, alternating arm and leg lifts and active trunk extension in the prone position should be performed. Finally, regular stretching to improve extension and rotation with trigger pointing can decrease muscle tension over the affected muscles. A thoracic wedge, which is designed to increase extension range of motion, can be used. The wedge is a hard piece of molded plastic or rubber with a wedge cut out to accommodate the spine. The patient lies on the ground with the wedge placed in between the shoulder blades. The patient is instructed to arch over it. Alternatively, two tennis balls can be taped together for the same effect. These exercises can be done before regular stretching to increase excursion. Regular massage therapy can maintain flexibility and prevent tightening from more regular exercise.

At the gym, progressive dynamic movements such as rowing, latissimus pull-downs, pull-ups, and an abdominal crunch strengthening program should be emphasized. Instruction in proper positioning and technique should

be provided to prevent further injury. Use of a “physio-ball” at home or at the gym can facilitate trunk extension as well as abdominal stretching and strengthening to increase overall conditioning of the thoracic cage and core musculature. This can be done in conjunction with use of Thera-Bands with progressive resistance to facilitate stretching of the arms and shoulders with mild strengthening of the shoulder, arm, and core muscles. Finally, a pool program can be prescribed. Swimming strokes such as the crawl, backstroke, and butterfly emphasize extension and can be very useful to prevent or to correct a flexion bias. With the crawl, patients are instructed to breathe on both sides to prevent unilateral strain in the neck and upper thoracic spine.

Procedures

Trigger point injections may help reduce focal pain caused by taut bands of muscle, allowing the patient to exercise to restore range of motion, to correct postural imbalance, and to increase strength and balance of the dysfunctional segment [18]. Acupuncture can be used for local as well as for systemic treatment. Finally, botulinum toxin type A (Botox) has been used for specific muscles, including rhomboids, trapezius, levator scapulae, and serratus, that often contribute to thoracic strain and sprain.

Although there are no studies specifically looking at the use of botulinum toxin type A for treatment of thoracic strain, there are studies that looked at treatment of regional myofascial pain disorders. One study showed effective pain relief for generalized myofascial pain syndrome [19]. In another study, there was no statistically significant improvement in pain with direct trigger point injections of patients with cervicothoracic myofascial pain syndrome [20]. A recent comprehensive review found inconclusive evidence on the use of botulinum toxin type A for muscle treatment, although some encouraging data are available [21].

Another possible treatment of myofascial pain syndrome that can be applied in thoracic sprain or strain cases is extracorporeal shock wave therapy. This may be an effective alternative to needling or medication infusion [22].

Surgery

Surgery is not usually indicated unless focal disc herniation with neurologic abnormalities such as radiculopathy (see Chapter 43) has occurred or there is instability of particular spinal segments from fracture or dislocation.

Potential Disease Complications

Thoracic sprain and strain injuries can occasionally develop into myofascial pain syndromes.

Potential Treatment Complications

Possible complications include gastrointestinal side effects from nonsteroidal anti-inflammatory drugs. Other possible complications include somnolence or confusion from muscle relaxants; addiction from narcotics; bleeding, infection, postinjection soreness, and pneumothorax from trigger point injections; excessive weakness and development

of antibodies from botulinum toxin; and temporary post-treatment exacerbation of pain from manual medicine or extracorporeal shock wave therapy [23].

SECTION VI

Low Back

CHAPTER 45

Lumbar Degenerative Disease

Michael K. Schaufele, MD

Jordan L. Tate, MD, MPH

Synonyms

Osteoarthritis of the spine
Spondylosis
Lumbar arthritis
Degenerative joint disease of the spine
Degenerative disc disease

ICD-9 Codes

721.3 Lumbosacral spondylosis without myelopathy
721.90 Spondylosis of unspecified site (spinal arthritis)
722.52 Degeneration of lumbar or lumbosacral intervertebral disc
724.2 Low back pain

ICD-10 Codes

M47.817 Spondylosis without myelopathy or radiculopathy, lumbosacral region
M47.899 Other spondylosis, site unspecified
M51.36 Other intervertebral disc degeneration, lumbar region
M51.37 Other intervertebral disc degeneration, lumbosacral region
M54.5 Low back pain

Definition

Degeneration of the anatomic structures of the lumbar spine is a process associated with aging. Degenerative processes may affect several anatomic structures, resulting in different clinical syndromes, or may be entirely asymptomatic. Approximately one third of asymptomatic and one half of symptomatic younger adults show degenerative changes on lumbar spine magnetic resonance imaging [1,2]. At ages older than 60 years, degenerative changes are found in more than 90% of adults [3]. Degeneration may be accelerated in patients with previous trauma or injury to the lumbar spine. Factors such as diabetes mellitus, smoking, and obesity have been associated with increased rates of lumbar spine degeneration. L4-L5 and L5-S1 are the most commonly involved lumbar levels, given that they undergo the greatest torsion and compressive loads during activity. There has not been a proven gender predominance; however, some studies suggest that disc degeneration may affect more men, whereas facet arthropathy may be more prevalent in women [4]. Genetic factors have been suggested to play a major role in determining presence and extent of spine degeneration [5]. Twin studies have shown heritabilities ranging from 52% to 68% for various lumbar disc degeneration phenotypes [6].

The intervertebral disc experiences progressive dehydration as part of the normal aging process. In certain patients, fissures in the anulus fibrosus may develop, causing an inflammatory response. Nociceptive pain fibers may grow into these fissures [7]. Further degeneration may result in progression of the disease or complete annular tears, which may be the source of discogenic low back pain, also referred to as internal disc disruption syndrome. Up to 39% of patients with chronic low back pain may suffer from internal disc disruption [8]. The loss of segmental integrity may lead to further degeneration of the disc, which results in narrowing

of the intervertebral disc space. Because of increased loads on the posterior elements, facet degeneration may develop.

The facet (zygapophyseal) joints and sacroiliac joints, like other synovial joints in the body, may develop osteoarthritis [9].

Facet arthropathy may be an independent or concurrent source of low back pain. Further disc degeneration and subsequent loss of disc height may cause subluxation of the facet joints, resulting in degenerative spondylolisthesis, most commonly at the L4-L5 level [10].

Other conditions seen with lumbar degeneration include spondylosis deformans and diffuse idiopathic skeletal hyperostosis. Spondylosis deformans is a degenerative condition marked by formation of anterolateral osteophytes and is mainly a radiologic diagnosis. In spondylosis deformans, the intervertebral spaces are usually well preserved, unlike in degenerative disc disease. The initiating factor in the development of this condition may be degeneration of the annulus fibrosus, primarily in the anterolateral disc space [11]. Spondylosis deformans may become clinically symptomatic if excessive osteophyte formation leads to neural compression, such as in spinal stenosis. Diffuse idiopathic skeletal hyperostosis involves ossification of the ligamentous attachments to the vertebral bones (entheses). Radiologic features consist of multilevel excessive anterior osteophyte formation. Diffuse idiopathic skeletal hyperostosis affects 5% to 10% of patients older than 65 years [12]. This diagnosis is typically an incidental finding on radiologic studies [13].

Other factors associated with lumbar degeneration include environmental, occupational, and psychosocial influences. Environmental influences include cigarette smoking and occupational activities that involve repetitive bending and prolonged exposures to stooping, sitting, or vibrational stresses. These repetitive actions may result in degeneration of the lumbosacral motion segments [12]. Psychosocial factors are well known to contribute to significant disability in low back pain, often in patients with only minimal structural impairment [14].

Symptoms

Lumbar degenerative symptoms range from minor to debilitating. Common complaints include chronic back pain and stiffness. Patients may also report limited range of motion, especially with extension in the case of facet arthropathy or spinal stenosis. Pain with lumbar flexion, coughing, sneezing, or Valsalva maneuver is often associated with disc disease. Should the degenerative changes result in compression of neural structures, patients may develop radicular symptoms into the leg. This can be seen in conditions such as lumbar disc herniations and spinal stenosis.

Lumbar degenerative disease is probably entirely asymptomatic in the majority of cases. Approximately one third of subjects have substantial abnormalities on magnetic resonance imaging despite being clinically asymptomatic [1]. Because of factors not well understood, such as leakage of inflammatory factors from the disc, a chronic pain syndrome may develop in some patients, possibly from repetitive sensitization of nociceptive fibers in the annulus fibrosus [15].

Clinicians should inquire about atypical symptoms of back pain, including night pain, fever, and recent weight loss. These may lead to the diagnosis of malignant neoplasm or infection.

Clinicians should also inquire about symptoms of chronic pain, including sleep disturbances and depression.

Physical Examination

The purpose of the physical examination is to direct further evaluation and therapy toward one of the five most common sources of low back pain: discogenic, facet arthropathy or instability, radiculopathy or neural compression, myofascial or soft tissue, and psychogenic. Combinations of these sources of back pain often exist. A diagnosis based on physical findings will allow the use of advanced diagnostic tests and therapeutic options in the most cost-effective approach.

A standardized low back examination should include assessment of flexibility (lumbosacral flexion, extension, trunk rotation, finger-floor distance, hamstring and iliopsoas range of motion, and hip range of motion). An inclinometer (Fig. 45.1) may assist in standardizing lumbar range of motion measurements [16]. A complete examination includes inspection of lower extremities for atrophy and vascular insufficiency, muscle strength testing, and assessment for sensory abnormalities and their distribution. It is important to note asymmetries in deep tendon reflexes (patellar tendon [L4], hamstring tendon [L5], and Achilles tendon [S1]), which may be the most objective finding. Upper motor neuron signs, such as Babinski and ankle clonus, should also be tested. Functional strength testing should include heel to toe walking, calf and toe raises, single-leg knee bends, and complete gait evaluation. Specific testing for lower back

FIGURE 45.1 Inclinometers can be used for true lumbar spine range of motion measurements (neutral position demonstrated).

Table 45.1 Waddell Signs

Five nonorganic physical signs are described by Waddell.

Tenderness	Nonorganic tenderness may be either superficial or nonanatomic. Superficial tenderness can be elicited by lightly pinching over a wide area of lumbar skin. Nonanatomic pain is described as deep tenderness felt over a wide area rather than localized to one structure.
Simulation test	This is usually based on movement that produces pain. Two examples are axial loading, in which low back pain is reported on vertical loading over the standing patient's skull by the clinician's hands, and rotation, in which back pain is reported when the shoulder and pelvis are passively rotated in the same plane as the patient stands relaxed with feet together.
Distraction test	If a positive physical finding is demonstrated in a routine manner, this finding is checked while the patient's attention is distracted. Straight-leg raising is the most useful distraction test. There are several variations to this test; most commonly, however, straight-leg raise is done in the supine position and then, while the patient is distracted, in the sitting position. This is commonly referred to as the flip test. However, one should keep in mind that biomechanically, the two positions are very different.
Regional disturbances	Regional disturbances involve a widespread area, such as an entire quarter or half of the body. The essential feature of this nonorganic physical sign is divergence of the pain beyond the accepted neuroanatomy. Examples include give-away weakness in many muscle groups manually tested and sensory disturbances, such as diminished sensation to light touch, pinprick, or vibration, that do not follow a dermatomal pattern. Again, care must be taken not to mistake multiple root involvement for regional disturbance.
Overreaction	Waddell reported that overreaction during the examination may take the form of disproportionate verbalization, facial expression, muscle tension, tremor, collapsing, and even profuse sweating. Analysis of multiple nonorganic signs showed that overreaction was the single most important nonorganic physical sign. However, this sign is also the most influenced by the subjectivity of the observer.

Modified from Geraci MC Jr, Allea JT. Physical examination of the spine and its functional kinetic chain. In Cole AJ, Herring SA, eds. *The Low Back Pain Handbook*. Philadelphia, Hanley & Belfus, 1997.

syndromes includes straight-leg raising, femoral stretch sign, dural tension signs, and sacroiliac joint provocative maneuvers (e.g., FABER, Gillet, Yeoman, and Gaenslen tests) as well as specific evaluation techniques, such as the McKenzie technique. Assessment of the patient for nonorganic signs of back pain (Waddell signs; [Table 45.1](#)) will help the clinician to recognize patients in whom psychological factors may contribute to the pain syndrome [17].

Functional Limitations

Functional limitations in degenerative diseases of the lumbar spine depend on the anatomic structures involved. All aspects of daily living, including self-care, work, sports activities, and recreation, may be affected.

Symptoms are typically exacerbated during bending, twisting, stooping, and forward flexion in patients with primary discogenic pain. Patients with facet arthropathy or instability report increased pain with extension-based activity, including standing and walking. Pain is often relieved with sitting and other similar forward-flexed positions. Patients with myofascial or soft tissue syndromes report pain that is worsened with static and prolonged physical activity. Symptomatic improvement may be associated with rest and modalities including heat, cold, and pressure. Patients with contributing psychological factors, such as depression and somatization disorders, typically report pain out of proportion to the underlying pathologic process, poor sleep, and significant disability in their daily activities.

Diagnostic Studies

Diagnostic testing is directed by the history and physical examination and should be ordered only if the therapeutic plan will be significantly influenced by the results. Anteroposterior and lateral lumbar spine radiographs are helpful for identifying loss of disc height as a result of disc degeneration, spondylosis or osteophyte formation, spondylolisthesis, scoliosis,

and facet arthropathy ([Fig. 45.2](#)). Oblique views are helpful to identify spondylolysis. Flexion-extension films are necessary to identify dynamic instability and can assist in the selection of appropriate surgical candidates for fusion procedures. Significant degenerative instability usually does not occur before the age of 50 years, but it should be included in the differential diagnosis in patients with clinical symptoms suggestive of advanced facet arthropathy and disc degeneration [11]. Magnetic resonance imaging of the lumbar spine is used because of its sensitivity for identification of abnormalities of the soft tissues and neural structures. It is particularly helpful in identifying various stages of degenerative disc disease as well as annular tears and disc herniation. Other significant sources of back pain, such as neoplasms, osteomyelitis, and fractures, can also be identified with magnetic resonance imaging. Computed tomography is a valuable diagnostic tool in assessing fractures and other osseous abnormalities of the lumbar spine. Computed tomographic imaging in combination with myelography (computed tomographic myelography) aids in presurgical planning by allowing identification of osseous structures causing neural compression, especially in spinal stenosis.

Discography is currently the only technique to correlate structural abnormalities of the intervertebral disc seen on advanced imaging studies with a patient's pain response. Reproduction of painful symptoms with intradiscal injection of radiopaque contrast material aids in the localization of specific disc levels as pain generators and can be useful in separating painful disc degeneration from painless degeneration. Exploratory studies on blockade of the sinuvertebral nerve, which is thought to carry nociceptive sensation to the intervertebral disc, have been undertaken as an alternative means for diagnosis of discogenic pain [18]. Electrodiagnostic studies may become necessary in cases of peripheral neurologic deficits not clarified by physical examination or imaging. They allow identification of compression neuropathy, radiculopathy, or systemic motor and sensory diseases.

FIGURE 45.2 Chronic degenerative changes—plain film. **A**, On a coned down lateral film, the L4-5 motion segment shows a vacuum phenomenon in the disc (*large arrow*), end-plate remodeling with large anterior spurs (*curved arrows*), and grade I retrolisthesis (*open arrow*). **B**, A standing lateral film shows multilevel degenerative disc disease with large posterior spurs, small anterior osteophytes, end-plate remodeling, and moderately severe disc space narrowing at L2-3, L3-4, and L4-5. (From Cole AJ, Herzog RJ. *The lumbar spine: imaging options*. In Cole AJ, Herring SA, eds. *The Low Back Pain Handbook*. Philadelphia, Hanley & Belfus, 1997.)

Differential Diagnosis (see also Table 45.2)

Radiculopathy
Spondylolysis, spondylolisthesis
Spinal stenosis
Tumors
Fractures (e.g., osteoporotic compression fractures)
Osteomyelitis of the spine, discitis

Treatment

Initial

The most important treatment of any low back pain condition is education and reassurance of the patient. Most of the acute low back symptoms are self-limited and typically resolve within 4 to 6 weeks. The mostly benign nature of degenerative conditions of the spine should be emphasized as well as the fact that acute exacerbations tend to improve over time regardless of therapy. Therapy is directed toward management of the symptoms rather than “cure” of the disease. Initial therapy for lumbar degenerative disease should consist of anti-inflammatory medications, muscle relaxants (Table 45.3), occasionally opioid medications for severe symptom exacerbation, and a functionally oriented physical therapy program. Most patients do well with these measures and do not require any invasive procedures. Other useful initial treatments may include trigger point injections as well as physical modalities such as heat and cold.

Low-dose tricyclic antidepressants can help with improvement of sleep.

Rehabilitation

Rehabilitation of lumbar degenerative disc disease includes a detailed assessment of functional limitations and functional goals for every patient. A full assessment of occupational and leisure activity demands and goals should also be obtained. For example, patients with advanced degenerative disc disease may benefit from early vocational rehabilitation and counseling with the goal of avoiding future occupational disability and surgical procedures.

On occasion, lumbar orthotics are prescribed, but these are generally not thought to be beneficial in the treatment of degenerative low back pain unless there is significant spondylolisthesis or some other specific indication.

Therapy goals focus on normalization of impairments in flexibility, strength, and endurance and should emphasize healthy lifestyle modifications. A basic lumbar stabilization program with a focus on posture, footwear modifications (if necessary), workplace modifications (if appropriate), and general conditioning works for most patients. Modalities such as ultrasound and electrical stimulation can be used for acute low back pain; however, the focus of supervised therapy should be on an active program rather than the passive treatment that modalities provide.

In patients whose condition does not improve with the outlined initial therapeutic measures, a more intensive, functional restoration approach may be helpful. This commonly

Table 45.2 Pseudospine Pain: Diagnostic Keys

	Condition	Diagnostic Keys
Vascular	Abdominal aortic aneurysm	Older than 50 years Abdominal and back pain Pulsatile abdominal mass
Gynecologic	Endometriosis	Woman of reproductive age Cyclic pelvic and back pain
	Pelvic inflammatory disease	Young, sexually active woman Systemically ill (fever chills) Discharge, dysuria
	Ectopic pregnancy	Missed period Abdominal or pelvic pain Positive pregnancy test result
Genitourinary	Prostatitis	Men older than 30 years Dysuria Low back and perineal pain
	Nephrolithiasis	Flank and groin pain Hematuria
Gastrointestinal	Pancreatitis	Abdominal pain radiating to back Systemic signs (fever, nausea, vomiting) Elevated serum amylase
Rheumatologic	Penetrating or perforated duodenal ulcer	Abdominal pain radiating to back
	Fibromyalgia	Young to middle-aged woman Widespread pain Multiple tender points Disrupted sleep, fatigue Normal radiographs and laboratory values
	Polymyalgia rheumatica	Older than 50-60 years Hip or shoulder girdle pain and stiffness Elevated erythrocyte sedimentation rate Dramatic response to low-dose prednisone
	Seronegative spondyloarthropathies (ankylosing spondylitis, Reiter syndrome, psoriatic, enteropathic)	Younger man (ankylosing spondylitis, Reiter syndrome) Lower lumbosacral pain Morning stiffness ("gel") Improvement with activity Radiographic sacroiliitis
	Diffuse idiopathic skeletal hyperostosis (Forestier disease)	Older than 50-60 years Thoracolumbar stiffness or pain Flowing anterior vertebral calcification
	Piriformis syndrome	Buttock and leg pain Pain on resisted hip external rotation and abduction
	Scheuermann kyphosis	Transgluteal or transrectal tenderness Age 12-15 years Thoracic or thoracolumbar pain Increased fixed thoracic kyphosis
	Trochanteric bursitis, gluteal fasciitis	3 or more wedged vertebrae with end-plate irregularities Pain or tenderness over greater trochanter
	Adult scoliosis	Back pain Uneven shoulders, scapular prominence Paravertebral hump with forward flexion
Metabolic	Osteoporosis	Woman older than 60 years Severe acute thoracic pain (fracture) Severe weight-bearing pelvic pain (fracture) Aching, dull thoracic pain; relieved in supine position (mechanical)
	Osteomalacia	Loss of height, increased thoracic kyphosis Diffuse skeletal pain or tenderness
	Paget disease	Increased alkaline phosphatase Bone pain: low back, pelvic, tibia Increased alkaline phosphatase
	Diabetic polyradiculopathy	Characteristic radiographic appearance Older than 50 years Diffuse leg pain, worse at night Proximal muscle weakness
Malignant neoplasia		Older than 50 years Back pain unrelieved by positional change—night pain Previous history of malignant disease Elevated erythrocyte sedimentation rate

Table 45.3 Commonly Used Drugs for Muscle Relaxation

Generic Name	Brand Name	Common Doses
Cyclobenzaprine	Flexeril	5-20 mg po tid
Carisoprodol	Soma	350 mg po tid
Baclofen	Lioresal	10-20 mg po q6h
Methocarbamol	Robaxin	500-750 mg po tid
Chlorzoxazone	Parafon Forte	250-500 mg po tid
Orphenadrine	Norflex	100 mg po bid
Metaxalone	Skelaxin	800 mg tid-qid

Modified from Schofferman J. Medications for low back pain. In Cole AJ, Herring SA, eds. *The Low Back Pain Handbook*. Philadelphia, Hanley & Belfus, 1997.

includes comprehensive physical rehabilitation with psychological support. These programs can be called many things (e.g., comprehensive spine program, chronic pain program, work conditioning program). Although most of these programs are traditionally considered later in the course of degenerative diseases, early referral may be helpful in decreasing related disability [19]. Another common functional rehabilitation technique is the dynamic lumbar stabilization approach [20]. This muscle stabilization program uses static and dynamic postural exercises to improve the patient's overall function. It includes education about proper body mechanics during activities of daily living, improved extremity strength and endurance, and muscle stabilization through gym training and healthy lifestyle activities. The hallmark of this program is that postural control is attained through pelvic tilting to control the degree of lumbar lordosis in a pain-free range. The program is designed to advance the patient toward increasingly demanding exercises and to incorporate these exercises into activities of daily living. The program progresses through the building of static strength into dynamic stabilization for patients with more physically demanding athletic activities and occupational demands. This program is supported by a home exercise program.

Core strengthening expands on the concept of lumbar stabilization and has become a key component of rehabilitation programs for all patients, not only for athletes. Core stability is the ability of the lumbo-pelvic-hip complex to prevent buckling and to return to equilibrium after perturbation. Although bone and soft tissues contribute, core stability is predominantly maintained by the dynamic function of the trunk musculature. Decreased core stability may predispose to injury, and appropriate training may reduce injury [21,22].

Postoperative rehabilitation should focus on strength retraining with increasing aerobic exercise while maintaining neutral spine alignment. There is no consensus on when to initiate rehabilitation after surgery, but strong evidence exists for enrolling patients in intensive programs within 6 weeks of surgery to improve functional outcomes and rates of return to work [23].

Procedures

Spinal injection procedures have become an increasingly important part of the overall treatment program for lumbar degenerative disease. These procedures have diagnostic, therapeutic, and even prognostic benefits. It is now

commonly agreed that injections should ideally be performed with x-ray guidance and contrast enhancement [24]. The most commonly used procedures are epidural steroid injections, which are beneficial primarily for temporary relief of radicular symptoms [25]. Injection techniques, such as the transforaminal approach, ensure that the medication, usually a corticosteroid, is delivered into the anterior epidural space [26]. Theoretically, medication delivery to the anterior epidural space would decrease inflammatory processes in local structures, such as degenerative discs. However, recent meta-analyses have found good evidence for epidural steroid injections for radicular pain but only fair evidence for axial pain. Moreover, studies have suggested that epidural injections with local anesthesia but without steroid have rates of efficacy similar to those of injections with steroid [27]. Facet (zygapophyseal joint) anesthesia can be obtained through injections done intra-articularly or by blocking the innervating nerves (medial branches) to these joints. Intra-articular facet injections may allow temporary pain relief in cases of synovitis and facet joint cysts. Medial branch injections are used to establish the diagnosis of facet-mediated pain by temporary blockade of the supplying nerve branches of the affected joint [28]. Medial branch neurotomies ("facet rhizotomies") by radiofrequency ablation may provide longer symptomatic relief for patients with clearly identified facet pain [29]. On occasion, intradiscal steroid injections are applied, but their use is debated because intradiscal steroid may cause discitis, progression of disc degeneration, and calcification of the intervertebral disc [30,31].

Minimally invasive intradiscal therapies (e.g., chemo-nucleolysis, laser, percutaneous disc decompression) have been used since the 1970s with various clinical successes. Treatment techniques including intradiscal electrothermal therapy involve controlled thermal application to the posterior anulus through an intradiscal catheter. Research data show conflicting results about the therapeutic efficacy of these treatment modalities [32]. There are promising biologic agents currently being studied (e.g., bone morphogenetic protein, mesenchymal stem cell, fibrin adhesive, juvenile chondrocytes) for injection into discs that aim to reverse degenerative and inflammatory changes. Animal studies have revealed augmentation of disc height on imaging studies after intradiscal administration of stem cells [33].

Surgery

The surgical indications for degenerative disc disease of the lumbar spine are highly debated and evolving. Some U.S. insurance companies have recently declared lumbar spine fusion surgery to not be medically necessary if the sole indication is degenerative disc disease. Most insurance carriers require prior authorization of lumbar spine fusion and will consider approval for surgery only when intensive nonsurgical therapy, including physical therapy, injection procedures, and semi-invasive procedures, have failed and the patient continues to have functionally limiting pain. Confounding psychological factors and mental disorders should be excluded before any surgical procedure [34]. Current data are incomplete to judge the scientific validity of spinal fusion for low back pain syndromes [35]. However, if the intervertebral disc is clearly identified as

the source of low back pain, interbody fusion with excision of the diseased disc appears to have favorable results. In general, surgical options include posterior fusion procedures with or without pedicle screw instrumentation, anterior interbody fusion with or without pedicle screws, and a combination of these procedures. In case of neural compression, additional decompression procedures may be required. Disc arthroplasty ("artificial disc") became available in the United States after more than a decade of positive experience in Europe [36,37]. The indication for this surgery is chronic low back pain due to symptomatic degenerative disc disease without significant radiographic instability, neural compression, and facet joint arthropathy. Current outcome studies do not show a clear benefit in pain and functional improvement over fusion surgeries, and questions about the longevity of the implants remain.

Recent developments in endoscopic and minimally invasive surgical techniques have expanded surgical management options. Current research maintains insufficient data for firm conclusions to be drawn about the therapeutic efficacy of these surgical techniques [38].

Potential Disease Complications

In general, degenerative lumbar disease is a benign condition. However, increasing functional limitations can occur, especially if advanced segmental degeneration leads to neural compression and symptoms of spinal stenosis, neural claudication, and segmental instability develop. Persistent neurologic deficits from these conditions are rare and can be avoided if the conditions are diagnosed early and appropriate treatment is begun. A small number of patients may develop chronic pain syndromes. Low back pain is the most common cause of the chronic pain syndrome. Not surprisingly, the incidence of mental disorders, such as depression and somatoform disorders, is high, and these disorders commonly respond better to a behavioral psychology approach than to disease-oriented medical treatment approaches. Early detection of patients with mental disorders will help avoid unnecessary medical treatment and allow appropriate psychological and psychiatric interventions.

Potential Treatment Complications

As with any medications, clinicians must be fully aware of their risks and unwanted side effects. Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Muscle relaxants can cause sedation. Low-dose tricyclic antidepressants can cause sedation and urinary retention in men with benign prostatic hypertrophy. Some patients require chronic opioid therapy, and issues of constipation and dependence arise. Risks associated with spinal injection include cortisone flare, hyperglycemia, dural puncture, and, rarely, hematoma, infection, and neurologic damage. All potential complications should be thoroughly discussed with the patient before treatment. Potential surgical complications, including nerve damage, malpositioned hardware, wound infection, and medical complications (pulmonary embolism, pneumonia, acute kidney injury), will vary with the procedure but can be as high as 17% for lumbar fusion procedures for degenerative disc disease [39].

Lumbar Facet Arthropathy

Ted A. Lennard, MD

Synonyms

Facet joint pain
Facet joint arthritis
Z-joint pain
Zygapophyseal joint pain
Apophyseal joint pain
Facet syndrome
Posterior element disorder

ICD-9 Codes

721.3 Lumbar spondylosis without myelopathy
721.90 Spondylosis of unspecified site (spinal arthritis)
724.2 Low back pain

ICD-10 Codes

M47.817 Spondylosis without myelopathy or radiculopathy, lumbosacral region
M47.899 Other spondylosis, site unspecified
M54.5 Low back pain

Definition

Lumbar facet joints are formed by the articulation of the inferior and superior articular facets of adjacent vertebrae (Fig. 46.1). These joints, located posteriorly in the spinal axis, are lined with synovium and have highly innervated joint capsules. Lumbar facet arthropathy refers to any acquired, traumatic, or degenerative process that changes the normal function or anatomy of a lumbar facet joint. These changes often disrupt the normal biomechanics of the joint, resulting in hyaline cartilage damage and ultimately periarticular hypertrophy. When they are painful, these joints may limit activities of daily living, work, and recreational sports. Lumbar facet joints may be a primary

source of pain, but they are often painful concomitantly with a degenerative or injured lumbar disc, fracture, or ligamentous injury.

Lumbar facet arthropathy is more severe at the L4-L5 level and is common with advancing age and progressive intervertebral disc disease. These findings are independent of race and sex [1,2]. Postsurgical facet joint pain appears to be associated with advancing age, prolonged intraoperative time, intraoperative complications, discectomy, history of recurrent disc prolapse, and lack of rehabilitation [3,4].

Symptoms

Patients often complain of generalized or lateralized spinal pain, sometimes well localized. Pain may be provoked with spinal extension and rotation, from either a standing or a prone position. Relief with partial lumbar flexion is common. In the lumbar spine, these joints may refer pain into the buttock or posterior thigh but rarely below the knee [5–7]. Neurologic symptoms, such as lower extremity weakness, numbness, and paresthesias, would be unexpected from a primary facet joint disorder.

Physical Examination

A detailed examination of the lumbar spine and a lower extremity neurologic examination are considered standard procedure for those thought to have facet arthropathy. Although no portion of the examination has been shown to definitively correlate with the diagnosis of a facet joint disorder, the physical examination can be helpful in elevating the clinician's level of suspicion for this diagnosis [8,9]. The examination starts with simple observation of the patient's gait, posture, movement patterns, and range of motion. Generalized and segmental spinal palpation is followed by a detailed neurologic examination for sensation, reflexes, tone, and strength. In the absence of coexisting pathologic processes, such as lumbar radiculopathy, strength, sensation, and deep tendon reflexes should be normal.

Provocative maneuvers and nerve tension tests, including straight-leg raising, should accompany the evaluation to rule out any superimposed nerve root injury that might accompany a facet disorder. The clinician notes the patient's response when the lower extremity is raised with the hip flexed and the knee extended. This "tension" placed on inflamed or injured lower lumbosacral nerve roots will provoke pain, paresthesias, or numbness down the extremity.

FIGURE 46.1 Posterior view of the lumbar spine demonstrating the paired facet joints. Note the thick capsule surrounding the facet joint. (Reprinted from [OrthoClick.com](#).)

Typically, in isolated cases of lumbar facet disorders, this maneuver does not provoke radiating symptoms into the lower extremity, but it may cause lower back pain. Some physicians find that facet pain can be reproduced with prone extension with rotation, hip extension, lumbar extension while standing on a single leg, and standing spinal extension.

Functional Limitations

Patients with lumbar facet joint arthropathy may experience difficulty with prolonged walking, stair climbing, twisting, standing, and prone lying. Because facet problems are common with underlying disc disease, patients often have difficulty with lumbar flexion activities, such as lifting, stooping, and bending.

Diagnostic Studies

Fluoroscopy-guided, contrast-enhanced, anesthetic intra-articular or medial branch blocks are considered the “gold standard” for the diagnosis of a painful lumbar facet joint (Figs. 46.2 and 46.3) [10–12]. Clinical history, examination findings, radiographic changes, computed tomography, magnetic resonance imaging, and bone scan have not been shown to correlate with facet joint pain [8,9,13].

Differential Diagnosis

- Internal disc disruption
- Myofascial pain syndrome
- Nerve root compression
- Radiculopathy
- Spondylolysis or spondylolisthesis
- Lumbar stenosis
- Spondylosis
- Sacroiliac joint dysfunction

Treatment

Initial

Initial treatment emphasizes local pain control with oral analgesics and nonsteroidal anti-inflammatory drugs, ice, topical creams, local blind periarticular corticosteroid injections, and avoidance of exacerbating activities. Spinal

manipulations and acupuncture may also reduce local pain. Temporary wearing of corsets and limited activity may be used.

Rehabilitation

Physical therapy may include modalities to control pain (e.g., ice, heat, ultrasound), traction, instruction in body mechanics, flexibility training (including hamstring stretching), articular mobilization techniques, core strengthening, generalized conditioning, and restoration of normal movement patterns. Critical assessment of the biomechanics of specific activities that may be job related (e.g., sitting at a desk, carpentry work, driving) or sports related (e.g., running, cycling) is important. This assessment can result in prevention of recurrent episodes of pain because changes in a technique or activity may reduce the underlying forces at the joint level. Simple ergonomic measures that act to support the lumbar spine during sitting and standing may reduce the occurrence of low back pain from the facet joints. These measures include proper chair height and design, properly designed work table, and adjustable chair supports. While standing, the addition of a footrest, pads, and the ability to change body position routinely may reduce low back pain.

Procedures

Intra-articular, fluoroscopy-guided, contrast-enhanced facet injections are considered essential in the proper diagnosis and treatment of a painful facet joint [10,11,14–17]. Ultrasound guidance for these procedures is an emerging option [18–21]. Patients can be evaluated before and after injection to determine what portion of their pain can be attributed to the joints injected. After confirmation with contrast material, 1 to 2 mL of an anesthetic-corticosteroid mix is injected directly into the joint. An alternative approach is to perform anesthetic medial branch blocks with small volumes (0.1 to 0.3 mL) of anesthetic. Recent data suggest that medial branch blocks may be the preferred method for diagnosis of facet joint pain [16,22,23]. If the facet joint is found to be the putative source of pain, a medial branch neurotomy may be desirable [24–26].

Surgery

Surgery is rare in primary and isolated facet arthropathies. Surgical spinal fusion may be performed for discogenic pain, which may affect secondary cases of facet arthropathies.

Potential Disease Complications

Because a common cause of facet arthropathy is degenerative in nature, this disorder is often progressive, resulting in chronic, intractable spinal pain [26]. It often coexists with spinal disc abnormalities, further leading to chronic pain. This subsequently results in diminished spinal motion and weakness.

Potential Treatment Complications

Treatment-related complications may be caused by medications; nonsteroidal anti-inflammatory drugs may cause gastrointestinal and renal problems, and analgesics may result

in liver dysfunction and constipation. Local periarticular injections and acupuncture may cause local transient needle pain. Local manual treatments or injections will often cause transient exacerbation of symptoms. Intra-articular facet injections will cause transient local spinal pain and swelling and possibly bruising. More serious injection-related complications include an allergic reaction to the medications, injury to a blood vessel or nerve, trauma to the spinal cord, and infection. When more serious injection complications occur, they can usually be attributed to poor procedure technique [10].

Lumbar Radiculopathy

Maury Ellenberg, MD

Michael J. Ellenberg, MD

Synonyms

Lumbar radiculitis

Sciatica

Pinched nerve

Herniated nucleus pulposus with nerve root irritation

ICD-9 Codes

724.4 Lumbar radiculopathy

722.22 Disc herniation

ICD-10 Codes

M54.16 Radiculopathy, lumbar region

M51.9 Unspecified thoracic, thoracolumbar, lumbosacral intervertebral disc disorder

Definition

Lumbar radiculopathy refers to a pathologic process involving the lumbar nerve roots. Lumbar radiculitis refers to an irritation or inflammation of a nerve root. These terms should not be confused with disc herniation, which is a displacement of the lumbar disc from its anatomic location between the vertebrae (often into the spinal canal) (Fig. 47.1). Although lumbar radiculopathy is often caused by a herniated lumbar disc, this is not invariably the case. Many pathologic processes, such as bone encroachment, tumors, and metabolic disorders (e.g., diabetes), can also result in lumbar radiculopathy. It is of utmost significance that disc herniation is often an incidental finding on imaging of the lumbar spine of asymptomatic individuals [1,2]. Therefore, without a clear correlation with the history and physical examination, imaging studies alone can be more misleading than beneficial. When disc herniation results

in radiculopathy, the precise cause of the pain is not fully understood. The two possibilities are mechanical compression and inflammation. It has been demonstrated that in a “nonirritated” nerve, mechanical stimulus rarely leads to pain. In contrast, an “irritated” nerve usually results in pain. Furthermore, inflammatory mediators have experimentally been shown to cause radicular pain in the absence of compression [3–5]. It is likely that both factors may be at work individually or together in any given patient. As a result of the imaging findings in asymptomatic individuals and the various causes of pain in radiculopathy, it should be no surprise that disc herniations and nerve root compression can be present in asymptomatic patients [2] and that patients can have radiculopathy without visible disc herniations or nerve root compression [6].

The prevalence of lumbar radiculopathy in the general population varies from 2.2% to 8%, depending on the study, and the incidence ranges from 0.7% to 9.6% [7,8]. One study found a higher incidence in men (67%), with the highest prevalence in individuals 45 to 65 years old [9], and an association with obesity and smoking as well as a correlation with occupations requiring very heavy physical activity.

Symptoms

The most common symptom in lumbar radiculopathy is pain, which may vary in severity and location. The pain may be severe and is often exacerbated or precipitated by standing, sitting, coughing, and sneezing. The location of the pain depends on the nerve root involved, with a great deal of overlap among the dermatomes. Most commonly, S1 radiculopathy produces posterior thigh and calf pain; L5, buttocks and anterolateral leg pain; L4, anterior thigh, anterior or medial knee, and medial leg pain; and L3, groin pain. The patient usually cannot pinpoint the precise onset of pain. Location of pain at onset may be in the back; however, by the time the patient is evaluated, the pain may be present only in the buttocks or limb.

Paresthesias are also common and occur in the dermatomal distribution of the involved nerve root (rarely is the sensory loss complete). On occasion, the patient may present with complaints of weakness. Rarely, there is bladder and bowel involvement, which may be manifested as urinary retention or bowel incontinence.

FIGURE 47.1 A herniated disc.

Physical Examination

The most important elements in the evaluation of lumbar radiculopathy are the history and physical examination [10]. A thorough musculoskeletal and peripheral neurologic examination should be performed. Examine the back for asymmetry or a shift over one side of the pelvis. Evaluate back motion and see whether radicular symptoms (pain radiating to an extremity) in the distribution of the patient’s complaints are produced. In an L5 or S1 radiculopathy, forward flexion of the back while standing is equivalent to a straight-leg raising test and may produce pain in the buttock or posterior thigh. In an L4 or L3 radiculopathy, extension may produce groin or anterior thigh pain.

Manual muscle testing is a vital part of the examination for radiculopathy. The major muscle weakness in relation to the nerve root involved is as follows: L3, hip flexors; L4, knee extensors and hip adductors; L5, hip abductors, knee flexors, ankle dorsiflexors, foot evertors, foot inverters, and great toe extensor; S1, ankle plantar flexors (Table 47.1).

Try to detect weakness in the distribution of two peripheral nerves arising from the same nerve root. Proximal muscle weakness in the appropriate nerve root distribution is useful in distinguishing bilateral radiculopathy from peripheral neuropathy.

The straight-leg raising test can be performed with the patient sitting or supine. The leg is raised straight up by the examiner, and the test result is positive if the patient complains of pain in the extremity (not the back), typically in a specific nerve root distribution. If pain occurs only in the back, this is not an indicator of radiculopathy and is most often seen with nonspecific low back pain. On occasion, the process of lumbar radiculopathy may start with low back pain, and several days or weeks later, the symptom will occur in the leg. It is possible that the initial process of nucleus pulposus rupture through the anulus may result in the initial back pain, but the pathogenesis is not completely known at this time. Compare side to side to confirm a positive response to the straight-leg raise as opposed to the pain associated with passive hamstring stretch. Rectal examination and perianal and inguinal sensory testing should be done if there is history of bowel or bladder incontinence or retention or recent onset of erectile dysfunction.

Waddell signs are a group of indicators that a nonorganic process is interfering with the accuracy of the physical examination. The signs are superficial—nonanatomic tenderness; simulation—axial loading or rotation of the head causes complaints of back pain; distraction—sitting straight-leg raising versus supine; regional disturbance—weakness or sensory loss in a region of the body that is in a nonanatomic distribution; and overreaction—what is described commonly as excessive pain behavior. These signs are often present in patients with compensation, litigation, or psychoemotional issues [11]. Evaluation for presence of Waddell signs should be a routine part of the examination in patients with pain complaints, particularly if they are long-standing or the history reveals that some of these issues are present.

Functional Limitations

The functional limitations depend on the severity of the symptoms and weakness. Limitations usually occur because of pain but may occasionally occur because of weakness. Standing and walking may be limited, and sitting tolerance is often decreased. Patients with an L4 radiculopathy are at risk of falling down stairs if the involved leg is their “trailing”

Table 47.1 Diagnosis of Lumbar Radiculopathy

Nerve Root	Pain Radiation	Gait Deviation	Motor Weakness	Sensory Loss	Reflex Loss
L3	Groin and inner thigh	Sometimes antalgic	Hip flexion	Anteromedial thigh	Patellar (variable)
L4	Anterior thigh or knee, or upper medial leg	Sometimes antalgic Difficulty rising onto a stool or chair with one leg	Knee extension, hip flexion and adduction	Lateral or anterior thigh, medial leg, and knee	Patellar
L5	Buttocks, anterior or lateral leg, dorsal foot	Difficulty heel walking; if more severe, then foot slap or steppage gait Trendelenburg gait	Ankle dorsiflexion, foot eversion and inversion, toe extension, hip abduction	Posterolateral thigh, anterolateral leg, and mid-dorsal foot	Medial hamstring (variable)
S1	Posterior thigh, calf, plantar foot	Difficulty toe walking or cannot rise on toes 20 times	Foot plantar flexion	Posterior thigh and calf, lateral and plantar foot	Achilles

(power) leg on the stairs. They would also have difficulty ascending stairs or rising from a seated position, depending on the degree of weakness (although that is not as dangerous as descending stairs). Patients with a severe S1 radiculopathy will be unable to run because of calf weakness, even when the pain resolves. Patients with L5 radiculopathy may catch the foot on curbs or, if weakness is severe, on the ground. They may require a brace (ankle dorsiflexion assist). In patients with acute radiculopathy that is severe, the pain will usually preclude them from a whole range of activities—household, recreation, and work. In the majority of patients, once the acute process is ameliorated, they can return to most activities except for heavy household and work activity. After about 3 to 6 months, they can return to all activities unless there is residual weakness, in which case they would be functionally limited as noted before, depending on the radiculopathy level.

Diagnostic Studies

Diagnostic testing takes two forms: one to corroborate the diagnosis and the second to determine the etiology. For simple cases, despite the current “rush toward imaging,” diagnostic testing is usually not needed and the clinical picture can guide the treatment. A history that includes trauma, cancer, bacterial infection, human immunodeficiency virus infection, or diabetes would be an indication for earlier diagnostic testing.

Electromyography

Electromyography and nerve conduction studies, when performed by an individual well versed in the diagnosis of neuromuscular disorders, can be valuable in the diagnosis of lumbar radiculopathy. They can also help with differential diagnoses and in clarifying the diagnosis in patients whose physical examination is not reliable. Electromyography has the advantage over imaging techniques of high specificity, and recordings will rarely be abnormal in asymptomatic individuals [12]. Electrodiagnostic studies, however, do not give direct information about the *cause* of the radiculopathy.

Imaging

Imaging techniques in relation to lumbar radiculopathy usually refer to lumbosacral spine radiography, computed tomography (CT) scan, and magnetic resonance imaging (MRI).

Plain radiography can be useful to exclude traumatic bone injury or metastatic disease. It allows visualization of the disc space but not the contents of the spinal canal or the nerve roots. CT and MRI allow visualization of the disc, spinal canal, and nerve roots (Fig. 47.2). There is a high incidence of abnormal findings in asymptomatic people, with rates of disc herniation ranging from 21% in the 20- to 39-year age group to 37.5% in the 60- to 80-year age group [2]. In fact, in one study, only 36% of asymptomatic individuals had normal discs at all levels. In other words, it is “normal” to have some disc abnormality, which occurs as part of normal aging [1]. To be meaningful, CT and MRI must clearly correlate with the clinical findings. Perform these studies if tumor is suspected or surgery is contemplated. They also

may be useful in precisely locating pathologic changes for transforaminal epidural steroid injection. The most accurate study is MRI, and gadolinium enhancement is not needed unless a tumor is suspected or the patient has undergone prior surgery. Gadolinium enhancement is useful postsurgically to distinguish disc herniation from scar tissue.

Differential Diagnosis

- Trochanteric bursitis
- Anserine bursitis
- Hamstring strain
- Lumbosacral plexopathy
- Diabetic amyotrophy
- Sciatic neuropathy
- Tibial neuropathy
- Peroneal neuropathy
- Femoral neuropathy
- Hip osteoarthritis
- Sacroiliitis
- Avascular necrosis of the hip
- Pelvic stress fracture
- Occult hip fracture
- Shin splints
- Lateral femoral cutaneous neuropathy (meralgia paresthetica)
- Spinal stenosis
- Cauda equina syndrome
- Demyelinating disorder
- Lumbar facet syndrome
- Piriformis syndrome
- Transient migratory regional osteoporosis

Treatment

Initial

The treatment goal is to reduce inflammation and thereby relieve the pain and allow resolution of the radiculopathy regardless of the underlying anatomic abnormalities. Bed rest, which had been the mainstay of nonoperative treatment, is now recommended only for symptom control. In previous studies, bed rest has not been shown to have an effect on the final outcome of the disorder [13]. As long as patients avoid aggravating activities or bending or lifting, which tend to increase intradiscal pressure, they can carry on most everyday activities.

Use nonsteroidal anti-inflammatory drugs (NSAIDs) to help reduce inflammation and to provide pain relief. NSAIDs have been shown to be effective in acute low back pain [14]. However, a review that included pooling of three randomized clinical trials using NSAIDs showed no effectiveness over placebo [15]. It is still reasonable to give NSAIDs a short trial in acute lumbar radiculopathy for pain relief, although they will not shorten the course of the disorder. The use of oral steroids remains controversial and has not passed the scrutiny of well-controlled studies, even in acute low back pain. In a recent meta-analysis of the use of NSAIDs, corticosteroids, tricyclic antidepressants, and anticonvulsants, although the pooled data showed no efficacy with any of these medications over placebo in chronic radiculopathy [16], there was one study that found short-term efficacy for gabapentin [17]. There were two studies

FIGURE 47.2 A, Normal disc. Note the concave posterior margin of the disc (arrows). B, Bulging disc. Image from a CT myelogram shows the broad-based margin of the bulging disc (arrows) pushing on the anterior thecal sac. C, Left posterior disc herniation (arrow). D, Right posterior disc herniation. The abnormal soft tissue from the herniated disc is seen in the right lateral recess on this CT myelogram (arrow). Note the normally opacified nerve root sheath on the contralateral side (open arrow). E, Herniated discs L4-L5 and L5-S1; the L4-L5 herniation is the larger of the two. There is posterior displacement of the low-signal posterior longitudinal ligament (arrow). (From Barckhausen RR, Math KR. *Lumbar spine diseases*. In Katz DS, Math KR, Groskin SA, eds. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

in patients with acute radiculopathy in which oral corticosteroids seemed to be effective in the short-term treatment of radicular pain [16]. Other medications, such as cyclobenzaprine, metaxalone, methocarbamol, and chlorzoxazone, some of which may have effectiveness in acute low back pain, have not been shown to be effective in acute radiculopathy [18].

Clinically, for acute radiculopathy, there are several options. If the pain is severe, early epidural steroid injection (see the section on procedures) and testing with imaging and electromyography are reasonable. Another option is oral steroids, such as methylprednisolone (Medrol) dose pack, and the use of opioids for short-term pain control. For more chronic radicular pain, it would be reasonable to try anticonvulsants, such as gabapentin, or a combination of gabapentin and a tricyclic antidepressant, such as amitriptyline or nor-

triptyline. Start treatment with a low dose and titrate up gradually to determine the minimally effective dose.

Opioids may be used for pain relief, although their effectiveness is suboptimal in neuropathic pain, with some suggestion that they should be used only in severe cases [19]. There is no major concern for addiction in acute care of patients who have not demonstrated past addictive behavior. The needs range from none to relatively high doses, such as the equivalent of 60 to 100mg of morphine (e.g., MS Contin) a day. Start with hydrocodone or oxycodone and titrate up as needed. For more severe pain, use a long-acting opioid, such as oxycodone (OxyContin) or MS Contin, and for breakthrough pain, use a shorter acting opioid, such as hydrocodone, oxycodone, or short-acting morphine. These treatments should be short term to avoid the risks of dependency or addiction. There seems to be no efficacy of opioids

versus placebo for symptom relief or decrease in disability in chronic radiculopathy [20].

Rehabilitation

With an acute painful radiculopathy, it is generally best to wait for some of the acute stage to subside before ordering physical therapy. In a longer standing problem, therapy may be the best first approach.

Physical methods are a useful adjunct to the medication treatment. Various methods, which include flexion and extension exercises (often called a lumbosacral stabilization program), have been tried. Whatever method is used, if radicular pain is produced, the exercises should be stopped. After the radiculopathy resolves, the patient should be prescribed a proper exercise regimen to improve flexibility and muscle strength. Lumbar stabilization exercises, core muscle strengthening, and remaining active may be the most effective of the various methods studied carefully in lumbar radiculopathy. One study showed no effectiveness of lumbar traction [21]. Other modalities, such as transcutaneous electrical nerve stimulation, acupuncture, massage, and manipulation, are not well studied with randomized clinical trials in lumbar radiculopathy [6]. Because they are not likely to cause injury, they can be given a short trial. The manipulation should be done cautiously.

Procedures

Epidural steroid injections are beneficial in acute radiculopathy in patients with or without disc herniation [21,22]. The results in chronic radiculopathy are less convincing. The most effective technique and material to be used for epidural steroid injection are controversial [23,24]. Some literature suggests that either steroid preparations or local anesthetics are superior to placebo for long-term effects. Short-term effects, however, favored the steroid group [24,25]. Some studies show that transforaminal epidural steroid injections have a marginally greater improvement in pain scores compared with lumbar epidural steroid injections. However, on the basis of the preferred safety profile, greater procedural comfort of lumbar epidural steroid injections, and nearly equal functional gains of the two procedures, a reasonable clinical approach is to attempt a lumbar epidural steroid injection initially and then, in the absence of significant improvement or resolution in 2 weeks, to attempt a transforaminal epidural steroid injection [22,23].

Whereas the scientific literature shows that the effects of these interventions are relatively short-lived [21,23], the intervention is beneficial because it limits opiate use [23] and referral for surgical management.

These procedures should be performed under fluoroscopic guidance [26]. It is advisable to perform one injection and to re-evaluate the patient in 1 or 2 weeks to determine whether further injections are required. It is not appropriate to perform a “series of three injections.” On the other hand, a maximum of three injections should be performed for any one episode of radiculopathy. It is reasonable to repeat this procedure for recurrent episodes of radiculopathy after 3 to 6 months.

Nonoperative treatment allows resolution of the radiculopathy in up to 90% of cases [15,27,28]. More interestingly,

studies have demonstrated that when radiculopathy is the result of disc herniation, the actual herniation will resolve in the majority of cases, and even when the herniation remains, the symptoms often will still abate [29–31].

Surgery

Surgery is appropriate under two conditions. First, surgery is performed on an emergency basis when a patient presents with a central disc herniation with bowel and bladder incontinence or retention and bilateral lower extremity weakness. In this very rare condition, a neurosurgeon or orthopedic spine surgeon must be consulted immediately and the patient operated on, preferably within 6 hours. Second, surgery is an option if a patient continues to have pain that limits function after an adequate trial of nonoperative treatment.

Patient selection is extremely important to achieve a good surgical outcome. The best outcomes occur in patients with single-level root involvement; with pain experienced more in the limb than in the back; and when an anatomic abnormality on imaging corresponds to the patient's symptoms, physical examination findings, and electromyographic findings in patients without psychological or secondary gain issues [32,33].

A recent update of a Cochrane review on the subject of surgery versus conservative care concluded that in selected patients, surgery can provide faster relief, but there remains no convincing evidence of a difference in long-term outcomes [34].

The type of surgery depends on the cause of the radiculopathy. For cases of disc herniation, simple laminectomy and discectomy suffice; there seems to be no difference between the standard, microdiscectomy, and newer minimally invasive procedures on outcome or time to return to activity [35]. Fusion should be avoided in these instances. With spinal stenosis, a more extensive laminectomy with foraminotomy may be needed. Fusion should be reserved for the relatively infrequent case of well-demonstrated spinal instability together with radiculopathy or if the surgical procedure will result in spinal instability. One study [36] suggested that fusion is needed in the case of spondylolisthesis, but this has not been confirmed with any randomized clinical trials.

Potential Disease Complications

Complications relate to involvement of the nerve roots in the cauda equina. The most serious is the “paraplegic disc.” In this case, the herniated disc can cause paralysis, but this is very rare. More common, but still unusual, is a disc that causes lower limb weakness and involvement of bowel and bladder function. Residual lower limb weakness may occur either spontaneously or after surgery. Patients may progress to a chronic low back pain syndrome; this is particularly likely to occur in patients with secondary gain issues.

Potential Treatment Complications

NSAIDs can cause gastrointestinal bleeding, mouth ulcers, and renal and hepatic complications. Newer cyclooxygenase 2 inhibitors may avoid gastrointestinal bleeding. There have

been associations attributed to the use of cyclooxygenase 2 inhibitors and other NSAIDs with cardiovascular disease. These medications should always be used cautiously, in proper doses, and for limited periods.

Corticosteroids, when used long term, have myriad complications, including weight gain, fat redistribution, osteoporosis, and diabetes mellitus, among others. The short-term use should cause few complications in healthy individuals. Those with diabetes will experience a rise in blood glucose concentration, and some patients may experience mental and emotional difficulties that can include psychosis. Steroids may also lead to gastrointestinal bleeding.

Use of opioids can lead to dependency in some patients. Although they may be of use in patients with lumbar radiculopathy, their use with low back pain and chronic nonmalignant pain, in which effectiveness is questionable [37], has led to an epidemic of the use and abuse of these drugs [38,39].

Epidural steroid injections can (rarely) result in epidural abscess and epidural hematoma. Patients should not take aspirin for 7 days before the injection. Some centers recommend that NSAIDs not be taken for 3 to 5 days before the procedure, although there is no literature documenting an increased incidence of bleeding complications from epidural or spinal injections when patients are taking NSAIDs. Warfarin should be discontinued, and if in doubt, the international normalized ratio should be checked. Clopidogrel (Plavix) and similar antiplatelet agents should be discontinued for a week before injection. The injection can produce local pain, and if it is performed without fluoroscopy, it can often result in spinal headache from piercing of the dura and a resultant spinal fluid leak. This occurs considerably less often when fluoroscopic guidance is used. Contamination of injectable material from a compounding pharmacy, has led to central nervous system infections, primarily with *Exserohilum rostratum*, and *Aspergillus*. Twenty-two other pathogens have also been identified. As of June 2013 this has resulted in 745 confirmed infections and 58 deaths. Currently the scope of regulatory oversight within the compounding industry is under review [40].

Surgical complications include infection, nerve root injury, paralysis, local back pain, and the usual postoperative complications (e.g., thrombophlebitis, bladder infection). More serious surgical complications include nerve root or cauda equine injury, arachnoiditis, and post-laminectomy pain syndromes. These complications may lead to repeated surgery, which may be more extensive.

CHAPTER 48

Low Back Strain or Sprain

Omar El Abd, MD
Joao E.D. Amadera, MD, PhD

Synonyms

Acute low back pain (“preferred terminology”)
“Pulled muscle” in the low back

ICD-9 Codes

- 722.10 Degenerative disc disease, lumbar spine
- 724.2 Low back pain
- 724.6 Sacroiliac joint disorder
- 724.8 Facet joint arthropathy

ICD-10 Codes

- M51.36 Other intervertebral disc degeneration, lumbar region
- M54.5 Low back pain
- M12.88 Other specified arthropathies, not elsewhere classified, vertebrae

Definition

Lumbar strain or sprain is a term used by clinicians to describe an episode of acute low back pain. The patients report pain in the low back at the lumbosacral region accompanied by contraction of the paraspinal muscles (hence, the expression “muscle sprain” or “strain”). The definite cause is unknown in most cases. It most likely is secondary to a chemical or mechanical irritation of the sensory nociceptive fibers in the intervertebral discs, facet joints, sacroiliac joints, or muscles and ligaments at the lumbosacral junction area.

Low back pain is a prevalent condition associated with work absenteeism, disability, and large health care costs [1]. Episodes of low back pain constitute the second leading symptom prompting patients to seek evaluation by a physician [2]. It is estimated that 50% to 80% of adults experience at least one episode of acute low back pain in their

lives [3,4]. The incidence of radiculopathy is reported to be much lower than the incidence of axial back pain at 2% to 6% [5]. Patients who experience acute back pain usually see improvements and are able to return to work within a month [6,7]. However, 2% to 7% of patients have chronic back pain [8,9]. Several studies suggest that 90% of patients with an acute episode of low back pain recover within 6 weeks [10–12]. In contrast, some well-conducted cohort studies demonstrate a less optimistic picture, providing short-term estimates of recovery ranging from 39% to 76% [13,14]. Pengel and colleagues [6] published a meta-analysis investigating the course of acute low back pain, concluding that both pain and disability improve rapidly within weeks (58% reduction of initial scores in the first month) and recurrences are common. On the other hand, more recently, Menezes and associates [1] demonstrated that the typical course of acute low back pain is initially favorable, with a marked reduction in mean pain and disability in the first 6 weeks. After 6 weeks, improvement slows, and only small reductions in mean pain and disability are apparent for up to 1 year. By 1 year, the average measures of pain and disability for acute low back pain were very low, suggesting that patients can expect to have minimal pain or disability at 1 year.

Clinicians encounter a number of patients who convert from acute pain to chronic pain. In a recent review involving 10 studies and more than 4000 participants, Hallegraef and coworkers [15] investigated adults with acute and subacute nonspecific low back pain. The odds that patients with negative recovery expectations will remain absent from work because of progression to chronic low back pain was two times greater than for those with more positive expectations.

Consequently, the goals of the clinician evaluating patients with an episode of acute low back pain are to have a working differential diagnosis of the condition and its etiology, to rule out radiculopathy or other serious medical causes, to have a rehabilitation plan that aims to prevent recurrence of this episode, to educate the patient about the pathologic process, and to formulate a management plan if the condition does not improve promptly.

Symptoms

The pain develops spontaneously or acutely after traumatic or strenuous events such as sports participation, repetitive bending, lifting, motor vehicle accidents, and falls. Pain is

Table 48.1 Red Flags

Symptom	Concern
Pain in the lower extremities (including the buttocks) more than pain in the lower back	Radiculopathy
Weakness or sensory deficit in one or both lower extremities	Radiculopathy and the possibility of cauda equina syndrome (especially if there is bilateral involvement of the lower extremities)
Bowel or bladder changes; saddle anesthesia	Cauda equina
Severe pain in the low back, including pain while lying down	Malignant neoplasm
Fever, chills, night sweats, recent loss of weight	Infection and malignant neoplasm
Injury related to a fall from a height or motor vehicle crash in a young patient or from a minor fall or heavy lifting in a patient with osteoporosis or possible osteoporosis	Fracture
History of cancer metastatic to bone	Malignant neoplasm

predominantly located in the lumbosacral area (axial) overlying the lumbar spinous processes and along the paraspinal muscles. There may be an association with pain in the lower extremities; however, the lower extremity pain is less intense than the low back pain. Pain is usually described as sharp and shooting in character accompanied by paraspinal muscle tightness.

Trunk rotation, sitting, and bending forward usually exacerbate pain. Lying down with application of modalities (heat or ice) usually mitigates it.

Red flags that require prompt medical response are outlined in [Table 48.1](#).

Etiology

Axial Pain (Pain Overlying the Lumbosacral Area)

Discogenic pain due to degenerative disc disease is the most common known cause of axial pain. The pain from the intervertebral discs is located in proximity to the degenerated disc. Multiple inflammatory products are found in the painful disc tissue that may increase the excitability of the sensory neurons. The pain is referred from the disc to the surrounding paraspinal and pelvic girdle muscles.

Facet (zygapophyseal) joint arthropathy is another source of axial pain, present in about 30% to 50% of patients describing axial pain in the lumbar as well as in the cervical spine [16–18]. The facets are paired synovial joints adjacent to the neural arches. Pain is predominantly in the paraspinal area and is accompanied by contractions of the muscles that guard around the facet joints. The pain from the facet joints can be unilateral or bilateral.

Sacroiliac joint arthropathy is a cause of axial back pain as well. The pain is located in the lumbosacral-buttock junction

with referral to the lower extremity and to the groin area. Painful conditions of the sacroiliac joint are known to result from spondyloarthropathies, infection, malignant neoplasms, pregnancies, and trauma and even to occur spontaneously.

Radicular Pain

Predominant buttocks area pain is a common presentation of lumbar radicular pain. Nerve roots can be affected secondary to mechanical pressure and inflammation. Mechanical pressure is usually secondary to disc protrusion (herniation) or due to spinal stenosis. Disc herniations involve all age groups, with predominance in the young and middle aged. Spinal stenosis, on the other hand, predominantly affects the elderly; it is a combination of disc degeneration, ligamentum hypertrophy, and facet arthropathy or spondylolisthesis. In radiculopathy, symptoms are present along a nerve root distribution. Sensory symptoms include pain, numbness, and tingling that follow the distribution of a particular nerve root. The symptoms may be accompanied by motor weakness in a myotomal distribution. Diagnosis and treatment of radiculopathy are discussed in Chapter 47.

Myofascial Pain

There are different theories explaining muscular reasons for acute low back pain, but they remain unproved [19,20]. These theories include inflammation—failure at the myotendinous junction and the production of an inflammatory repair response; ischemia—postural abnormalities causing chronic muscle activation and ischemia; trigger points secondary to repetitive strain of muscles (this theory remains the most attractive) [20]; and muscle imbalance.

The currently most accepted theory for muscle pain is related to the myofascial pain syndrome, which is a common reported disorder in chronic conditions but can be present in the acute conditions as well [21]. It is characterized by myofascial trigger points—hard, palpable, discrete, localized nodules located within taut bands of skeletal muscle and painful on compression. An active myofascial trigger point is associated with spontaneous pain, in which pain is present without palpation. This spontaneous pain can be at the site of the myofascial trigger points or remote from it. The current diagnostic standard for myofascial pain is based on palpation for the presence of trigger points in a taut band of skeletal muscle and an associated symptom cluster that includes referred pain patterns [22]. Treatment of myofascial pain involves massage, needling of the myofascial trigger points (with or without anesthetic injections), acupuncture, and stretching [23].

Referred Pain

Musculoskeletal structures in proximity to the spine and organs in the abdomen and pelvis are potential sources of pain with referral to the spine and the paraspinal area.

Occult Lesions

These lesions may be manifested with axial or radicular symptoms or with both. Spine metastasis [24] and spine and paraspinal infections are considered a rare possibility.

Skilled history taking and physical examination are necessary in diagnosis of these dangerous conditions.

Physical Examination

The physical examination starts with a thorough history to ascertain the pain's onset, character, location, and aggravating and mitigating factors. Inquiry about associated symptoms, such as weakness, bowel or bladder symptoms, fever, and abnormal loss of weight, and past medical

history are important. Examination includes inspection of the lower back and the lower extremities. Palpation of the paraspinal muscles, lumbar facet joints, inguinal lymph nodes, and lower extremity pulses is performed. Hip examination, root tension signs, discogenic provocative maneuvers, and sacroiliac joint maneuvers are performed (Table 48.2). Gait examination, with heel and toe walking, is assessed. Sensory examination and thorough manual muscle testing are performed. Deep tendon reflexes are examined.

Table 48.2 Spine Physical Examination Maneuvers

Maneuver	Description	Significance
Pelvic rock	In a supine position, flex the patient's hips until the flexed knees approximate to the chest; then, rotate the lower extremities from one side to the other.	Lumbar discogenic pain provocation
Sustained hip flexion	In a supine position, raise the patient's extended lower extremities to approximately 60 degrees. Ask the patient to hold the lower extremities in that position and release. The test result is positive on reproduction of low lumbar or buttock pain. Then lower the extremities successively approximately 15 degrees and, at each point, note the reproduction and intensity of pain.	Lumbar discogenic pain provocation
Root tension signs—upper extremity Spurling maneuver	Contralateral neck lateral bending and abduction of the ipsilateral upper extremity Passively perform cervical extension, lateral bending toward the side of symptoms, and axial compression.	Reproduces cervical radicular pain in the periscapular area or in the upper extremity Reproduces cervical radicular pain in the periscapular area or in the upper extremity
Straight-leg raise	While the patient is lying supine, the involved lower extremity is passively flexed to 30 degrees with the knee in full extension.	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Reverse straight-leg raise	While the patient is lying prone, the involved lower extremity is passively extended, the knee flexed.	Reproduces pain in the buttock and anterior thigh in conditions with high lumbar (such as L3 and L4) radicular pain
Crossed straight-leg raise	While the patient is lying supine, the contralateral lower extremity is passively flexed to 30 degrees with the knee in full extension.	Reproduces pain in the ipsilateral buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Sitting root test	While the patient is sitting, the involved lower extremity is passively flexed with the knee extended.	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Lasègue sign	While the patient is lying supine, the involved lower extremity is passively flexed to 90 degrees.	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Bragard sign	While the patient is lying supine, the involved lower extremity is passively flexed to 30 degrees, with dorsiflexion of the foot.	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Gaenslen maneuver	The patient is placed in a supine position with the affected side flush with the edge of the examination table. The hip and knee on the unaffected side are flexed, and the patient clasps the flexed knee to the chest. The examiner then applies pressure against the clasped knee, extends the lower extremity on the ipsilateral side, and brings it under the surface of the examination table.	Reproduces pain in patients with sacroiliac joint syndrome
Sacroiliac joint compression	Apply compression to the joint with the patient lying on the side.	Reproduces pain in patients with sacroiliac joint syndrome
Pressure at sacral sulcus	Apply pressure on the posterior superior iliac spine (dimple).	Reproduces pain in patients with sacroiliac joint syndrome
Patrick test (FABER test)	While the patient is supine, the knee and hip are flexed. The hip is abducted and externally rotated.	Reproduces pain in patients with sacroiliac joint syndrome, facet joint arthropathy (pain is reproduced in the low back), and degenerative joint disease of the hip (pain is reproduced in the groin)
Yeoman test	While the patient is in the prone position, the hip is extended and the ilium is externally rotated.	Reproduces pain in patients with sacroiliac joint syndrome
Iliac gapping test	Distraction can be performed to the anterior sacroiliac ligaments by applying pressure to the anterior superior iliac spines.	Reproduces pain in patients with sacroiliac joint syndrome

Diagnostic Studies

Without clinical signs of serious disease, diagnostic imaging and laboratory testing are not required [25,26]. However, imaging is recommended in the presence of red flags (such as history of trauma, constitutional symptoms, suspicion of radiculopathy, history of cancer, or persistent symptoms lasting longer than 1 month without improvement), in rheumatologic conditions, with prolonged use of steroids, and in the case of litigations.

The “gold standard” for evaluation of painful spine conditions is magnetic resonance imaging (MRI), which allows good visualization of discs and nerves as well as provides valuable information necessary for further management if the condition does not improve. MRI evaluation is required only if symptoms persist for longer than 1 month or at the onset of radicular pain or weakness. It is also used in the workup for back pain accompanied by constitutional symptoms.

Differential Diagnosis

- Degenerative disc disease
- Facet joint arthropathy
- Lumbar radiculopathy
- Sacroiliac joint syndrome
- Acute vertebral compression fracture
- Sacral stress fracture
- Referred pain from abdomen or pelvis
- Occult lesions in the spine, such as metastasis or infection

Treatment

Initial

Although there are numerous treatments for lumbar sprain and strain, most have little evidence of benefit. Inflammation is a major culprit of pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) are a cornerstone of pain management and should be provided in adequate doses. The selective cyclooxygenase 2 (COX-2) inhibitors show fewer gastric side effects compared with traditional NSAIDs; however, studies have shown that COX-2 inhibitors are associated with increased cardiovascular risks in specific patient populations [27].

Muscle relaxants are beneficial [26] and commonly used for pain management along with NSAIDs. These medications do not target a particular pathologic process and should be used in conjunction with NSAIDs. They are particularly helpful in improving sleep and relieving muscle “spasms” or “tightness” in patients with low back pain. Tramadol and opioid medications can be used in cases of severe pain, but an association between early receipt of opioids for acute low back pain and poor outcomes such as need for surgery and risk of receiving late opioids was found in a large cohort study [28]. If there is a need for extended use of these medicines, imaging studies should be performed and other management modalities should be considered. Modalities such as heat and ice can also be used.

Bed rest is not recommended in management of acute low back pain. It is advisable to remain active as much as possible [29].

In a recent review, no substantial benefit was shown with oral steroids, acupuncture, massage, traction, lumbar supports, or regular exercise programs in management of acute low back pain. Manipulative therapy, such as spinal manipulation and chiropractic techniques, is no more effective than established medical treatments, and adding it to established treatments does not improve outcomes [26].

Rehabilitation

The cornerstone for a complete recovery and the prevention of a recurrence of lumbar strain or sprain or the transformation to chronic low back pain is participation in a regular spine stabilization program. The program should begin immediately after the pain starts to improve. Initiation of an exercise program while the patient is experiencing severe symptoms is not helpful because the patient’s ability to participate is limited by pain. Exercises directed by a physical therapist, such as spine stabilization exercises, may decrease recurrent pain and need for further health care services and expenses [30,31]. A lumbar stabilization exercise program consists of stretching the lower extremities, pelvis, and lumbosacral muscles as well as performing exercises to strengthen the lumbosacral muscles. Postural training and learning proper body mechanics are essential. Patients are taught to perform these exercises and are advised to incorporate them into their daily routine.

Acupuncture

Acupuncture is widely used to treat patients with low back pain. A systematic review of the literature concluded that acupuncture is effective for pain relief and functional improvement in chronic back pain for a short term, but for acute back pain, no evidence of the effectiveness of acupuncture was found [32].

Procedures

Spinal injections are not considered a first-line management of acute low back pain. If progressive radiculopathy is suspected and the MRI study is consistent with this diagnosis, therapeutic spinal nerve root blocks should be promptly considered. In axial acute low back pain, if conservative management fails in 4 weeks, MRI is performed. If the MRI findings and the clinical findings suggest intervertebral disc disease, transforaminal epidural steroid injections or interlaminar epidural steroid injections are used. In this context, if MRI findings are unremarkable and pain persists, therapeutic facet joint injections or sacroiliac joint injections are used.

Surgery

Surgical intervention is not indicated in the management of acute low back pain without radiculopathy causing progressive neurologic deficits.

Potential Disease Complications

Most patients will recover within 2 weeks. However, if symptoms change from axial low back pain to radicular pain,

weakness develops in one or both lower extremities, or pain persists, the clinician should promptly order imaging studies. Further management is required as soon as possible to prevent deterioration of the patient's condition.

Potential Treatment Complications

Traditional NSAIDs used in management have resulted in gastrointestinal complications, such as peptic ulcer disease. Patients must take the medications with food, antacids, or ulcer-preventing medications. COX-2 inhibitors are associated with increased cardiovascular risks and should be taken for only short periods.

Muscle relaxants, tramadol, and opioids have sedative side effects. Patients are advised to refrain from driving and operating machinery while taking these medications.

Definition

Spondylolysis refers to a bone defect in the pars interarticularis. *Pars interarticularis* translates to “bridge between the joints” and as such is the isthmus or bone bridge between the inferior and superior articular surfaces of the neural arch of a single vertebra (Figs. 49.1 and 49.2). When bilateral spondylolysis is present, the posterior aspect of the neural arch, including the inferior articular surfaces, is no longer connected by bone to the rest of the vertebra.

Spondylolysis is an acquired condition; it has never been found at birth [1]. Spondylolysis is most commonly acquired early in life [2,3] and is identified by lumbar radiographs in 4.4% of children 5 to 7 years of age [2,4]. By 18 years of age, 6% of the population has spondylolysis [2], with few additional cases thought to occur thereafter. The prevalence remains steady at approximately 6% in radiographic screening of adult spines [5,6]. Community population prevalence ranges from 5.7% to 11.5% when screening is performed by computed tomography (CT) scan [6,7].

Spondylolysis most commonly occurs at the L5 vertebrae, where about 90% of the cases are found. It is found with decreasing frequency at progressively higher lumbar levels [2,8,9]. It is more common in males than in females with roughly a 2:1 ratio (7.7%-9% vs 3.1%-4.6%) [6-8,10], can be unilateral (less common) or bilateral (more common), and has a suspected genetic predisposition [2,10,11].

The most likely cause of spondylolysis is a stress fracture of the pars that persists as a nonunion [12]. This is consistent with the higher incidence of spondylolysis suspected in adolescents and young adults who aggressively participate in sports requiring repetitive flexion-extension movements, such as gymnastics, throwing sports, football, wrestling, rugby, judo, dance, and swimming breast and butterfly strokes. Specifically among gymnasts, those with spondylolysis tend to be heavier, older, or training with more intensity. The incidence of spondylolysis is as high as 30% in professional soccer and baseball players in Japan [5].

FIGURE 49.1 Spondylolysis of L5 with L5-S1 spondylolisthesis (arrow).

FIGURE 49.2 Meyerding classification of spondylolisthesis into grades based on the amount of slippage of the superior vertebral body on the vertebral body below.

Further supporting an acquired stress fracture as the cause is the lack of spondylolysis in the lumbar spines of individuals who have never walked [13].

Spondylolisthesis refers to displacement of a vertebral body in relation to the one below it. The most common type of spondylolisthesis, and the alignment abnormality that is implied when the term is used in this chapter, is an anterior displacement, also called anterolisthesis. Spondylolisthesis

Table 49.1 Etiology of Spondylolisthesis

Type	Etiology
Dysplastic	Congenital dysplasia of one or more facet joints
Isthmic (spondylolytic)	Bilateral pars defects (bilateral spondylolysis)
Degenerative	Degeneration of the facet joints and intervertebral discs
Traumatic	Fractures of posterior elements other than the pars
Pathologic	Malignant neoplasm, infection, or primary bone disease

can also occur in a posterior direction, called retrolisthesis, or laterally, called laterolisthesis. Spondylolisthesis is an abnormal finding. Whenever spondylolisthesis is present, it is pathognomonic of structural and functional failure of the neural arch and facet joints, which are responsible for maintaining normal vertebral alignment.

Spondylolisthesis is classified by etiology and grade. There are five etiologic types (Table 49.1):

Dysplastic spondylolisthesis results from congenital dysplasia of one or more facet joints.

Isthmic or spondylolytic spondylolisthesis results from bilateral pars defects (bilateral spondylolysis).

Degenerative spondylolisthesis results from degeneration of the facet joints and intervertebral discs (most common at L4-L5 and with advancing age).

Traumatic spondylolisthesis results from fractures of posterior elements other than the pars, such as facet joints, laminae, or pedicles.

Pathologic spondylolisthesis results from pathologic changes in posterior elements due to malignant neoplasm, infection, or primary bone disease.

Isthmic spondylolisthesis is male predominant, whereas degenerative spondylolisthesis is more common in females [7]. This chapter is limited to discussion of spondylolytic (isthmic) spondylolisthesis.

The grade of spondylolisthesis is rated by the percentage of slippage of the posterior corner of the vertebral body above over the superior surface of the vertebral body below. At least 5% slippage must be present for a diagnosis of spondylolisthesis to be conferred. Slippage can be further categorized into five grades: grade I indicates slippage from 5% to 25%; grade II is 26% to 50%; grade III is 51% to 75%; grade IV is more than 75% [14]; and grade V is complete dislocation of adjacent vertebrae, also called spondyloptosis. Most cases (60%-75%) are classified as grade I; 20% to 38% are classified as grade II; and less than 2% of all cases are graded III, IV, and V [8,15]. Slip of 15% or more is associated with increased risk of radicular pain or weakness [16] and is always associated with moderate to severe degeneration of the lumbosacral disc [10].

In children and adolescents with bilateral spondylolysis, spondylolisthesis is already present in 50% to 75% at the time of initial diagnosis of the spondylolysis [10,11,17,18]. The incidence of spondylolisthesis increases with age. After diagnosis, concern about the progression of spondylolisthesis is common but prognostic factors are lacking, making it difficult to predict which patients are at risk for progression [10,18]. However, participation in competitive sports has

not been found to influence the progression of spondylolisthesis [10]. In addition, unilateral spondylolysis almost never progresses to spondylolisthesis [10]. Whereas spondylolysis is male predominant [7], spondylolisthesis and slippage are more common in females when bilateral spondylolisthesis is present on CT [19]. Typically, progression occurs before and during the early teenage years [2], and only minor progression occurs after skeletal maturity [10]. Advancing age may lead to slight additional progression of spondylolytic spondylolisthesis, which is usually attributed to progressive degeneration of the disc and facet joints [20]. There is a positive correlation between the percentage of slip and the degree of degenerative change but no correlation with disc herniation [10].

Symptoms

Most people with spondylolysis and spondylolisthesis are asymptomatic. Less than 5% of children diagnosed with spondylolysis or spondylolisthesis have back pain before the age of 18 years [10]. Whereas the incidence of back pain increases with age, the incidence of back pain in those with spondylolysis or spondylolisthesis is similar to that of the general population [2,8,10,16]. In addition, the reverse is true: those with and without back pain have nearly an identical incidence of spondylolysis [21]. Furthermore, the degree of spondylolytic spondylolisthesis is not associated with the prevalence of back pain [10], and no study has linked progression of spondylolisthesis with pain symptoms. Disability because of back pain is no more prevalent in the population with spondylolysis and spondylolisthesis than in the general public [10,17]. Ultimately, in patients with established spondylolysis, with or without spondylolisthesis, it is difficult to attribute pain symptoms to these abnormalities.

One exception is the child or adolescent who initially presents with acute back pain, in whom reactive changes to the bone marrow from spondylolysis or spondylolisthesis likely contribute to the patient's symptoms. For these patients and others with back pain from associated spondylolysis or spondylolisthesis, no distinct pain characteristics have been found to distinguish their pain from that experienced by others with common degenerative back disorders [2,17]. The back pain can range from mild to severe and is frequently described as a dull, aching pain in the back, buttocks, and posterior thigh [2].

Spondylolysis with spondylolisthesis combined with disc degeneration may result in significant narrowing of the neuroforamina at the affected level. This can cause compression or irritation of the exiting spinal nerve, resulting in radiating pain and neurologic sequelae in the lower limb, often in dermatomal or myotomal distribution. Because spondylolytic spondylolisthesis most commonly involves the L5-S1 level, the L5 nerve is most often affected by this problem.

Physical Examination

The physical examination in spondylolysis and spondylolisthesis has few specific or sensitive findings. Painful trunk range of motion is often noted with children and adolescents with symptoms from acute spondylolysis. It is suspected that pain with trunk extension may be common in acute spondylolysis as this motion shifts load to the posterior

vertebral elements and thus through the region of the pars [22]. Indeed, limited range of motion for trunk extension has been observed [15,23]. However, the precision of painful trunk extension has not been determined, and these findings are common to other spinal disorders. Palpation of the back may reveal local tenderness at the lumbosacral junction, the level at which spondylolysis is most common [15].

Detection of spondylolisthesis on physical examination is difficult except in the rare cases of grade III or greater slips. Here, a "step-off" of the spinous processes can be seen or palpated at the level of the spondylolisthesis. In grade I and II spondylolisthesis, the step-off is much more difficult to detect and has never been shown to be a reliable finding. Neurologic deficits and positive results of straight-leg raising tests are rarely found in cases of spondylolytic spondylolisthesis, including cases with sciatica [15]. When neurologic deficits are noted, they usually involve the L5 roots, which can become irritated within their neuroforamina, presenting as an L5 radiculopathy (weakness of the extensor hallucis longus and hip abductors as well as sensory loss on the dorsum of the great toe) [15,24,25].

Diagnostic Studies

The lateral oblique radiograph may reveal the classic "collar on the Scottie dog" finding of spondylolysis (Fig. 49.3). This represents the bone defect between the inferior and superior articulating processes. The sensitivity of this view approaches only 33% because the plane of the pars defect must be close to the plane of the radiographic image to be

FIGURE 49.3 Spondylolysis defect of L5 noted on oblique radiograph. (arrow). Compare the intact pars at L4. (arrowhead). (From Slipman CW, Derby R, Simeone FA, Mayer TG. *Interventional Spine: An Algorithmic Approach*. Philadelphia, WB Saunders, 2008.)

clearly visualized [26]. The lateral radiograph reveals the presence and grade of spondylolisthesis.

Because of its ability to clearly visualize bone, CT is considered superior to magnetic resonance imaging (MRI) for direct visualization of the pars interarticularis, and some advocate CT axial images as the test of choice (Fig. 49.4) for identifying spondylolysis [27]. Even with CT, pars defects can be difficult to identify because they can simulate the adjacent facet joints. However, they usually lack the regular cortical surfaces of the facets [28]. Also useful is trying to identify an intact cortical ring for each vertebra, including the vertebral body, the pedicles, the pars, and the posterior neural arch. If the intact ring is not found in any of the cuts through the levels of the pedicles, a defect in the ring at the appropriate position suggests diagnosis of spondylolysis [29]. If spondylolysis is suspected when CT is ordered, scanning can be done with thin sections or reverse gantry angle to ensure optimum visualization of the pars [27].

For children and adolescents with acute spondylolysis, MRI with fat saturation technique can identify subtle bone marrow edema of early stress injury to the pars interarticularis [30]. Identifying the bone defect of the pars is more

challenging with MRI. Defects are most commonly noted as a lack of bone continuity between the superior and inferior articulating process on sagittal T1 images. MRI has a sensitivity of 57% to 86% (Fig. 49.5) [31]. Axial T2 MRI demonstrating increased fluid in the facet joints is also sensitive for early detection of spondylolisthesis (Fig. 49.6) [32]. Combining both of these MRI methods increases the sensitivity for detection of spondylolisthesis to 94%. MRI is also useful for grading spondylolisthesis and for visualizing the neuroforamina. As spondylolisthesis progresses, the neuroforamina become horizontally oriented, resulting in a position of the exiting spinal nerve that is between the pedicle above and the uncovered disc below. As the disc degenerates and loses height, foraminal narrowing is exacerbated, which may entrap the exiting spinal nerve. This is well visualized on T1 sagittal and axial images as the high fat signal that normally surrounds the spinal nerve becomes obliterated [25].

Bone scintigraphy uses radioisotopes that accumulate in metabolically hyperactive bone. Acute spondylolysis will reveal the bone activity of attempted healing. Long-standing spondylolysis with an established nonunion reveals no such activity [33]. Single-photon emission computed

FIGURE 49.4 Spondylolysis defects of L5 as seen on parasagittal (A) and axial (B) computed tomographic scans. (arrows). Note the lack of complete vertebral ring on axial view. (From Slipman CW, Derby R, Simeone FA, Mayer TG. *Interventional Spine: An Algorithmic Approach*. Philadelphia, WB Saunders, 2008.)

FIGURE 49.5 MRI of spondylolytic spondylolisthesis. Discontinuity of the vertebral ring is demonstrated (arrows) on the axial T2 image (left), and discontinuity of the pars is seen (arrow) on the parasagittal T1 image (right). Compare the elongated, horizontally oriented neuroforamina at L5-S1.

FIGURE 49.6 MRI of degenerative spondylolisthesis at L4-L5 (*left*). Increased T2 signal is demonstrated in axial view of the L4-L5 facet joints (*right*).

FIGURE 49.7 Child with back pain. **A**, Whole-body imaging shows scoliosis and a focal lesion at the right side of mid lumbar spine. SPECT/CT confirmed bilateral spondylolysis with increased activity. **B**, Fused SPECT/CT shows a spondylolysis with focal increased activity in the right L3 pars. **C**, Fused SPECT/CT shows a spondylolysis with focal increased activity in the left L4 pars. **D**, Three-dimensional CT image shows deficiency of posterior spinous processes in the lumbar spine from previous laminectomy that may have produced the altered stress that led to development of the bilateral spondylolysis. (From Nadel H. Pediatric bone scintigraphy update. *Semin Nucl Med* 2010;40:31-40.)

tomography (SPECT) improves the localizing ability of bone scintigraphy (Fig. 49.7). SPECT creates a series of slices through the target structure, permitting spatial separation of overlapping bone. Because of these abilities, SPECT imaging has established its place for the evaluation of adolescent athletes with back pain [34,35]. Nonetheless, MRI is considered a first-line imaging modality, given that it demonstrates a high level of agreement with SPECT in diagnosis of juvenile spondylolysis [36] without exposing the patient to radiation.

Differential Diagnosis

- Degenerative low back pain
- Lumbar disc herniation
- Discitis
- Lumbar radiculopathy
- Spinal stenosis (central vs neuroforaminal)
- Vertebral fracture (by compression, tumor, infection)
- Lumbar sprain or strain

Treatment

Initial

In children or adolescents with acute symptomatic spondylolysis as suggested by bone scintigraphy, SPECT, or MRI, attempts to induce or to aid healing are warranted. Nonoperative treatments for spondylolysis include bracing, activity restriction, and therapeutic exercises [37]. Rigid antilordotic bracing for 3 to 6 months (often for 23 hours a day) has been advocated to reduce stress on the pars interarticularis [38]; however, a more recent meta-analysis found that although 83.9% of nonoperatively treated patients clinically improve, there is not a difference between those treated with and without bracing [37]. Activity modification is usually recommended until symptoms subside, and physical therapy for trunk muscle strengthening has been used. With this approach, symptoms improve in about 75% of children, and many lytic defects are noted to heal [38]. Unilateral defects are more likely to heal than bilateral defects [37]. With nonoperative treatment of spondylolysis, children and young adults return to a pain-free or nearly pain-free state in unrestricted activities 84% of the time [37].

A similar approach is advocated in children and adolescents with concurrent spondylolisthesis. However, once spondylolisthesis is present, healing of the pars defect becomes improbable. In this situation, the goal is symptom reduction, and good results are observed in many patients. Nonoperative treatment does not specifically lead to a bone union in terminal defects but may alleviate symptoms [37]. To date, there is no evidence to support bracing for the prevention of slip progression. In cases of incidental findings of spondylolisthesis, there is no need for treatment or restriction of activities, including aggressive sports [12,39].

In adults with spondylolysis, with or without spondylolisthesis, back pain complaints are treated like other nonspecific back pain disorders. Such treatment includes education, analgesics, nonsteroidal anti-inflammatory drugs, exercise, avoidance of bed rest, and rapid return to activities [40–42].

Rehabilitation

Exercise has received some study as a treatment of symptomatic spondylolysis and spondylolisthesis. One study has advocated flexion over extension exercise [43], although methodologic shortcomings limit the strength of these recommendations. A spinal stabilization exercise program was found to be superior to uncontrolled treatment at short- and long-term follow-up [44]. Aggressive physical therapy programs for those with back pain including spondylolysis or spondylolisthesis have been shown to provide significant short-term benefit in terms of flexibility, strength, endurance, pain tolerance, and level of disability. This type of program consists of stretching and high-intensity, progressively resistive exercise training, performed in a non-pain-contingent manner [45,46]. Stretching targets the hip flexors, hamstrings, quadriceps, and gastrocnemius-soleus muscles. Strengthening targets the abdominal and various back muscles. Active individual therapy and functional restoration program participation both improve work ability and hasten return to sports and leisure activities; the functional restoration program participation improves endurance in treatment of chronic low back pain [47].

A randomized controlled trial comparing fusion surgery with intensive rehabilitation for chronic low back pain, including patients with spondylolisthesis, found that both approaches led to symptom improvement and suggested there was no clear evidence that surgery is more beneficial [48]. With the complications and cost of surgery, this minimal difference is worth considering in choosing a treatment approach [48].

For lumbosacral pain in general, in addition to exercise, cognitive interventions allowing patients to feel safe while being active lead to improvements in fear-avoidance beliefs and forward bending ability in patients with chronic back pain [49]. It has been suggested that the specific type of exercise may be less important than the general message exercise conveys—that normal use of the back is not harmful [50]. A randomized trial of rehabilitation methods after spinal fusion has demonstrated that early postoperative implementation of a combination of motor training exercise and cognitive-behavioral therapy is safe and results in superior functional outcomes compared with a customary exercise program of strength, flexibility, and cardiovascular exercises, including in patients with spondylolisthesis [51].

Alternative therapies such as massage [52] and therapeutic horseback riding [53] have been considered potentially beneficial treatments at the case report level. Modalities including ultrasound and electrical stimulation have not been shown to improve symptoms and are generally of limited value.

Procedures

Various types of spinal injections are given with use of fluoroscopy to ensure proper needle placement (Fig. 49.8). Anesthetic agents may be used for short-term pain relief, usually for diagnostic purposes. Injection of steroids may be tried for longer term therapeutic purposes in adults with

FIGURE 49.8 Fluoroscopic injection of pars interarticularis defect, with contrast material filling the pseudojoint capsule.

symptomatic spondylolysis or spondylolisthesis. For radicular pain, epidural injections may be used if the site of nerve root compression lies within the spinal canal, whereas selective nerve root blocks may be used if compression lies within the transforaminal space. For axial pain, facet injections may be used if the facet joints themselves are thought to be the source of pain.

Surgery

Referral to a surgeon is indicated in cases of spondylolisthesis causing progressive neurologic deficit; cauda equina compression with leg weakness, sensory loss, or bladder or bowel incontinence; neurogenic claudication; and persistent and severe back and leg pain despite aggressive conservative treatment. However, the patient's preference, age, and comorbidities must be considered before surgery because rates of reoperation range from 7% to 15% with a perioperative mortality of 0.5% to 1.3% [54–56]. In general, lumbar spinal decompression or fusion is usually indicated only when imaging studies correlate well with the history and physical examination findings. Surgical outcomes are generally favorable [57].

Potential Disease Complications

Most cases of spondylolysis and spondylolisthesis are asymptomatic and remain that way [58]. The intervertebral disc and facet degeneration that occurs naturally with age is accelerated in the presence of spondylolysis. Because of this, spondylolytic spondylolisthesis can progress and result in spinal nerve compression or spinal stenosis [59].

Potential Treatment Complications

Nonsteroidal anti-inflammatory drugs can cause gastric bleeding and renal and hepatic toxicity. Acetaminophen, in large amounts, can cause hepatic toxicity. Narcotic analgesics are potentially addictive, and because studies of the low back pain population have not found significant differences between narcotics and nonsteroidal anti-inflammatory drugs in terms of pain relief, extreme caution should be used beyond the short term [60]. Exercise can irritate spinal tissue already inflamed. Spinal injections may result in a temporary increase in pain, spinal headache, infection, spinal nerve damage, or spinal cord damage. Surgical decompression or fusion can lead to infection, failed fusion, persistent back pain, spinal nerve damage, or spinal cord damage. Lumbar stabilization can accelerate adjacent level degeneration [61].

ICD-10 Code

M48.06 Spinal stenosis, lumbar region

Definition

Lumbar spinal stenosis is classically defined as narrowing of the spinal canal, nerve root canals, or tunnels of the intervertebral foramina at the lumbar level [1]. A significant portion of the general population may have anatomic spinal stenosis without symptoms. Studies have indicated that 20% to 25% of asymptomatic people older than 40 years have significant narrowing of the lumbar spinal canal [2]. Stenosis causes symptoms only when there is sufficient impingement on neural structures, including the cauda equina or exiting nerve roots. Therefore spinal stenosis as a clinical entity is considered significant only if it results in symptomatic pain and compromised function.

The significant anatomic elements of the lumbosacral spine include the five lumbar vertebrae L1 to L5, the sacrum, the intervertebral discs, the ligamentum flavum, the zygapophyseal joints, the lumbar spinal nerve rootlets, the spinal nerve roots, and the cauda equina (Fig. 50.1).

Various schemes for classification of spinal stenosis have been devised and are listed in Table 50.1.

Congenital lumbar spinal stenosis is less common, representing 9% of cases [3]; symptoms first appear in patients during their 30s. Achondroplastic dwarves often have stenosis secondary to hypoplasia of the pedicles. Acromegaly may cause spinal stenosis by enlargement of the synovium and cartilage, which results in decreased cross-sectional area of the canal. Symptomatic spinal stenosis secondary to purely isolated congenital causes is rare. More commonly, patients will have a combination of congenital and acquired stenosis; a developmentally smaller canal predisposes them to symptoms once acquired changes occur to the surrounding anatomy. Developmental factors that lead to a small canal include statistically significantly shorter pedicles and a trefoil-shaped canal.

The acquired types of spinal stenosis are numerous, but degenerative is the most common. The first stage in the degenerative process is generally degradation of the hydrophilic proteoglycans within the intervertebral disc, attendant disc desiccation, and loss of disc height. This causes a shift of load onto the posterior structures of the canal, in particular the facet joints, which normally provide 3% to 25% of the support during axial loading but may bear up to 47% with degeneration of the disc [4]. As the facets bear more of the burden, they undergo degeneration, one aspect of which is osteophyte formation. This further diminishes the cross-sectional area of the canal and can also result in stenosis of the neural foramina (termed *foraminal stenosis*). The ligamentum flavum undergoes buckling with decreased intervertebral disc height, leading to further encroachment of the canal. Epidural fat may contribute to reduced canal space in some patients [5]. Patients can have degenerative facet synovial cysts that focally can encroach on the spinal canal and nerve rootlets and cause radicular pain.

Spinal stenosis can be differentiated by anatomic location, including central canal, lateral recess, foraminal, and extraforaminal (Table 50.2). Additional subcategorization includes division of the lateral canal into three regions: entrance zone, mid-zone, and exit zone.

Canal Measurements

The normal adult central canal has a midsagittal diameter of at least 13mm. Relative stenosis is defined as a canal

FIGURE 50.1 Normal anatomic structures of the lumbar spine at the third through the fifth lumbar levels. Note the close association between the nerve roots and the dural tube, the ligamentum flavum, the facet joints, the pedicles, and the lamina. The ligamentum (interlaminar ligament) attaches laterally to the facet capsules.

Extraforaminal

diameter between 10 and 13 mm; patients may or may not be symptomatic. Absolute stenosis occurs at a diameter of less than 10 mm, and patients are usually symptomatic. Extraforaminal nerve root compression can occur with disc herniation, degenerative scoliosis, or isthmic spondylolisthesis. Far-out syndrome, described by Wiltse and colleagues [6], involves L5 root impingement between the L5 transverse process and sacral ala in patients with spondylolisthesis. Extension of the spine can reduce foraminal cross-sectional area by 20% and central canal volume by up to 67% [7].

Finally, spinal stenosis has been categorized according to the patient's presenting pain syndrome of mechanical back pain, radicular pain, or neurogenic claudication. The pain pattern can be an indication of the anatomic and pathophysiologic mechanism of the patient's particular case of spinal stenosis.

Symptoms

Patients with acquired lumbar spinal stenosis usually have symptoms during their 50s and 60s. Symptomatic lumbar spinal stenosis may result in both back pain (from axial components, such as facet degeneration) and leg pain (from radicular components of nerve root compression, either central or lateral). Leg pain is often greater than back pain, and depending on which nerve roots are impinged, leg pain can be unilateral or bilateral and monoradicular or polyradicular. Patients with acquired, degenerative lumbar spinal stenosis tend to have a history of chronic low back pain and develop leg pain later in their course. In a study of 100 patients with lumbar spinal stenosis, back pain had been present for an average of 14 years and leg pain for an average of 2 years [8]. The classic symptom of lumbar spinal stenosis is neurogenic claudication, also known as pseudoclaudication, which typically is manifested as buttock, thigh, and calf pain exacerbated with walking, standing, or lumbar extension and alleviated with sitting, lying, or lumbar flexion. Symptoms also commonly involve cramping, numbness, tingling, heaviness, and spasms. Because the spinal canal and neural foramina widen with flexion and become narrower with extension, pain often improves with squatting and walking tolerance increases with a flexed posture, such as while walking uphill or on an inclined treadmill or while pushing a shopping cart. From a diagnostic point of view, neurogenic claudication was found in one study to have a sensitivity of 63% and a specificity of 71% compared with a combination of clinical, radiologic, and imaging test findings [9].

Symptoms that have been reported to have high sensitivity for lumbar spinal stenosis are as follows: best posture with regard to symptoms is sitting (89%) [10], worst posture with regard to symptoms is standing or walking (89%) [10], pain below buttocks (88%) [11], pain in legs worsened by walking and relieved by sitting (81%) [10], radiating leg pain (81%) [9], and age older than 65 years (77%) [11]. Symptoms with high specificity for lumbar spinal stenosis include no pain when seated (93%) and symptoms improved when seated (83%) [11]. A systematic review of the accuracy of the clinical history (the information in this sentence is about symptoms and not about findings in clinical examination) for the diagnosis of lumbar spinal stenosis, encompassing four studies and 741 patients, found that having no pain when seated (likelihood ratio [LR], 7.4; 95% confidence interval [CI], 1.9-30), improvement of symptoms when bending forward (LR, 6.4; 95% CI, 4.1-9.9), presence of bilateral buttock or leg pain (LR, 6.3; 95% CI, 3.1-13), and neurogenic claudication (LR, 3.7; 95% CI, 2.9-4.8) were the most useful individual findings for identifying the syndrome of lumbar spinal stenosis.

Physical Examination

Unlike the history, no physical examination findings are considered classic for lumbar spinal stenosis. Abnormal findings in lumbar spinal stenosis are similar to those in other disorders that cause peripheral neurologic deficits, but they are often not present. On physical examination, having a wide-based gait (LR, 13; 95% CI, 1.9-95) and an abnormal Romberg test result (LR, 4.2; 95% CI, 1.4-13) also increased the likelihood of the clinical syndrome of lumbar spinal stenosis. On the other hand, absence of neurogenic claudication (LR, 0.23; 95% CI, 0.17-0.31) decreased the likelihood of the diagnosis [12]. In the study by Amundsen and colleagues [8], abnormal findings within the 100-subject cohort included sensory dysfunction (51%), diminished deep tendon reflexes (47%), positive Lasègue test result (24%), and leg weakness (23%), among others. Physical and functional findings with high sensitivity include longer recovery time after level versus inclined treadmill walking (82%) [10] and no pain with lumbar flexion (79%) [11]. Highly specific aspects of examination and testing include improved walking tolerance on inclined versus level treadmill (92%), earlier onset of symptoms on level versus inclined treadmill (83%) [10], absent Achilles reflex (78%), lower extremity weakness (78%), pinprick or vibration deficit (>75%), wide-based gait (>75%), and presence of Romberg sign (>75%) [11]. Checking arterial pulses is important and necessary in patients thought to have lumbar spinal stenosis, but it is not sufficient to rule out arterial disease. A prospective study examining the rate of peripheral arterial disease in patients with intermittent claudication with concurrent lumbar spinal canal stenosis found that peripheral arterial disease was present in 26% of the subjects. Screening for peripheral arterial disease by ankle-brachial index and toe-brachial index tests should be considered in patients with intermittent claudication and lumbar spinal stenosis [13].

Functional Limitations

Worsening leg and back pain from walking, back extension, and prolonged standing is the primary contributor to activity limitation. As such, patients with lumbar spinal stenosis tend to have difficulties with walking long distances, going down stairs, and household or yard work (e.g., dishwashing, lawn mowing, and vacuuming) as well as with tasks that require overhead work (which may induce spinal extension). Balance deficits from sensory deficits may increase fall risk.

Diagnostic Studies

Diagnostic studies can provide useful information on structural and neurologic changes associated with spinal stenosis, but they must be interpreted in the context of the patient's clinical presentation. Several studies have demonstrated that there is no correlation between radiologic findings and clinical or functional outcomes [14]. However, another study found that severity of lumbar spinal stenosis as measured on functional myelography predicted long-term disability independent of therapeutic intervention [15]. The various qualities of the diagnostic tests are summarized in Table 50.3.

Differential Diagnosis

Lumbar spondylosis without spinal stenosis
Cervical and thoracic spinal stenosis
Herniated nucleus pulposus
Lumbar facet syndrome
Vertebral fracture with significant deformity or retropulsed fragments
Peripheral vascular disease
Venous claudication after thrombosis
Myxedema claudication
Inferior vena caval obstruction
Sacroiliac dysfunction
Osteoarthritis of the hips and knees
Trochanteric bursitis
Anterior tibial compartment syndrome
Spinal tumors
Conus medullaris and cauda equina neoplasms
Neurofibromas, ependymomas, hemangioblastomas, dermoids, epidermoids, lipomas
Metastatic spread of tumor
Peripheral neuropathy
Peripheral nerve entrapment
Restless legs syndrome
Stroke
Myofascial pain syndrome
Epidural abscess
Inflammatory arachnoiditis

Treatment

Initial

There is an overall lack of high-quality prospective controlled studies examining the efficacy of various noninvasive treatments of lumbar spinal stenosis. Moreover, many of the existing recommendations are in regard to back pain in general, without differentiation of pain associated specifically with lumbar spinal stenosis. Therefore much of clinical practice is based on extrapolation of recommendations, anecdotal experience, and expert opinion.

The oral analgesics used in lumbar spinal stenosis are acetaminophen, nonsteroidal anti-inflammatory drugs, muscle relaxants, anti-neuropathic pain medications including anticonvulsants and antidepressants, tramadol, and opioids. However, a number of systematic reviews have evaluated the use of pain medications in nonspecific low back pain. The review by Mens [23] stated that acetaminophen, nonsteroidal anti-inflammatory drugs, and mild opioids are potential first-line drugs, but there is no evidence that one is more effective than another. Nonbenzodiazepine muscle relaxants were listed as second-line drugs for acute low back pain. The efficacy of these medications for the treatment of symptomatic lumbar spinal stenosis is still unclear, and the sedating quality of these medications poses an increased risk of adverse events in elderly patients. Antidepressants with mixed-receptor or predominantly noradrenergic activity, including tricyclics, bupropion, venlafaxine, and duloxetine, are somewhat effective [24]. First-generation (e.g., carbamazepine and phenytoin) and second-generation (e.g., gabapentin and pregabalin) antiepileptic drugs are also somewhat effective.

Table 50.3 Comparison of Various Diagnostic Tests for Lumbar Spinal Stenosis

Imaging Method	Pertinent Findings	Advantages	Disadvantages	Accuracy
Plain radiography	Anteroposterior view: narrow interpedicular distance (normally 23-30 mm) [8] Lateral view: decreased canal width Ferguson view: far-out syndrome [18] Facet degeneration, cyst formation Ligamentum flavum ossification Intervertebral disc space narrowing Vertebral body end-plate osteophyte	Inexpensive Easy to obtain Can rule out gross bone disease	Poor soft tissue visualization	Sensitivity 66% and specificity 93% compared with plain CT as reference [18]
Plain myelography	Ventral extradural defects: caused by disc protrusions and vertebral end-plate osteophytes Lateral or posterior extradural defects: caused by facet osteophytes Hourglass constriction: indicates central stenosis	Shows sagittal plane	Invasive May need several dye injections for high-grade stenosis Limited view of foramen Contraindicated in patients with contrast allergy, alcoholism, seizures, phenothiazine intake [18]	71.8% correlation with surgical findings [16] Sensitivity 54%-100%; equivocal compared with CT or MRI Specificity slightly higher than that of CT or MRI
Plain computed tomography (CT)	Fat plane obliteration at exiting root Canal shape (trefoil vs round or ovoid) Pedicle length—direct measurement	Relatively inexpensive Axial view Superior bone detail	Poor soft tissue visualization Higher radiation exposure vs other imaging techniques	83% correlation with surgical findings [16] Sensitivity 74%-100%
Computed tomographic myelography	As above Useful in degenerative scoliosis or history of prior instrumentation	Visualization of central and lateral canals	Invasive Higher radiation exposure vs other imaging techniques	Sensitivity 87% [17] Comparable to MRI
Magnetic resonance imaging (MRI)	Disc degeneration: dark on T2 Annular tears: bright on T2 Stenosis and herniations in central and foraminal zones well visualized Evaluation of spine and spinal cord tumors	Noninvasive Shows sagittal plane Good soft tissue visualization	Interference from ferromagnetic implants Limitations on patient's body size, need to lie still, claustrophobia Expensive and time-consuming	83% correlation with surgical findings [16] Sensitivity 77%-87% Three-dimensional magnetic resonance myelography sensitivity 100% As accurate as CT myelography [19]
Electrodiagnostics	Bilateral multilevel lumbosacral radiculopathy is most common diagnosis Paraspinal mapping electromyography score >4 [20] Tibial F wave and soleus H reflex latencies after exercise [21,22]	Can evaluate for peripheral neuropathy and entrapments as well as progression of neurologic impairment Can rule out other neuromuscular disease	Significant interpretation bias May be difficult to differentiate lumbar spinal stenosis from other multiroot diseases (e.g., arachnoiditis) Patient discomfort or pain Expensive and time-consuming	Abnormal study in 78%-97% of patients with stenosis Paraspinal mapping electromyography score >4: specificity 100% and sensitivity 30%

Rehabilitation

To our knowledge, there are no randomized controlled trials in which the effectiveness of physical or manual therapies in the treatment of patients specifically with lumbar spinal

stenosis is evaluated. General recommendations include relative rest (avoidance of pain-exacerbating activities while staying active to minimize deconditioning) and a flexion-biased exercise program, including inclined treadmill and exercise bicycle. Flexion biasing increases the cross-sectional area

of the spinal canal compared with exercises performed in neutral or extension, thereby maximizing activity tolerance [25]. Whitman and associates [26] reported a case series of three patients who demonstrated significant improvements in pain and function at 18 months after undergoing specialized physical therapy programs that included spinal manipulation, flexion and rotation spine mobilization exercises, hip joint mobilization, hip flexor stretching, muscle retraining (lower abdominal, gluteal, and calf muscles), body weight–supported ambulation, and daily walking with properly prescribed orthotics. Body weight–supported ambulation acts to decrease the axial loading of the spine to increase the cross-sectional area of the neural foramina, and studies have provided some support of this strategy [27]. Physical modalities such as cold or hot packs, ultrasound, iontophoresis, and transcutaneous electrical nerve stimulation may be helpful, but data of clinical efficacy are lacking. Physicians and therapists must be aware of any medical comorbidities, such as cardiovascular and pulmonary disease, osteoporosis, cognitive deficits, and other musculoskeletal or neuromuscular conditions, that may have an impact on therapy tolerance. A retrospective analysis of predictors of walking performance and walking capacity showed that body mass index, pain, female sex, and age predict walking performance and capacity in people with lumbar spinal stenosis, those with low back pain, and asymptomatic control subjects. The authors of this analysis concluded that obesity and pain are modifiable predictors of walking deficits that could be targets for future intervention studies aimed at increasing walking performance and capacity in both the low back pain and lumbar spinal stenosis populations [28].

Procedures

Recommendations for the use of nonsurgical interventional procedures in the symptomatic control of lumbar spinal stenosis, particularly fluoroscopically guided epidural steroid injections, are somewhat controversial. A systematic review by Abdi and colleagues [29] concluded that for interlaminar, transforaminal, and caudal epidural steroid injections, there is strong evidence for short-term relief and limited to moderate evidence for long-term relief of lumbar radicular pain. A number of studies have cited short-term success rates of 71% to 80% [30,31] and long-term success rates of 32% to 75% [30,32]. Furthermore, symptomatic management with epidural steroid injections may delay surgery an average of 13 to 28 months [33,34]. A randomized controlled trial found that patients with lumbar central spinal stenosis received significant pain relief and improved their Oswestry disability scores after receiving lumbar interlaminar injections with or without steroids [35]. A study looking at the effects of fluoroscopic transforaminal epidural steroid injections in patients with degenerative lumbar scoliosis combined with spinal stenosis and radicular pain found them to be a more effective short-term option compared with lidocaine injections [36]. In general, epidural steroid injections can be considered a safe and reasonable therapeutic option for symptomatic management before surgical intervention is pursued.

Surgery

Patients with persistent symptoms despite conservative measures may benefit from surgical treatment. There are no

universally accepted indications for and contraindications to surgery. A key feature in the selection of patients is ensuring that the symptoms indeed arise from nerve root compression. It is also important to screen for depression. A prospective clinical study of lumbar spinal stenosis patients who underwent surgery found at 2-year follow-up that patients with depressive symptoms had poorer surgical outcomes than those with normal mood [37]. Surgery generally consists of decompressive laminectomy with medial facetectomy. The decompression relieves central canal stenosis; the medial facetectomy and attendant dissection along the lateral recesses decompress areas of foraminal stenosis.

The Maine Lumbar Spine Study [38] prospectively examined the outcome of initial surgical versus nonsurgical treatment in 148 patients at 1, 4, and 8 to 10 years. Rates of improvement in predominant symptom, low back pain, and leg pain at 1 year ranged from 77% to 79% in the surgery group and 42% to 45% in the nonsurgical group. At 8- to 10-year follow-up, the rates dropped to 53% to 67% in the surgery group and remained essentially stable at 41% to 50% in the nonsurgical group. As such, the benefits from surgery diminished over time, although improvements in leg pain and back-related functional status were maintained. A time-dependent decrease in benefit among older patients was evident in another study by Yamashita and colleagues [39]. In patients requiring surgery, earlier intervention is associated with improved long-term outcomes [38,40].

The Spine Patient Outcomes Research Trial compared the outcomes of patients who underwent surgical management of lumbar spinal stenosis with the outcomes of those who underwent conservative treatment. They found that at 2-year follow-up and at 4-year follow-up, intention-to-treat analysis showed significant improvement in SF-36 bodily pain and Oswestry disability index from baseline in the surgical group compared with the nonsurgical group. In addition, comparative effectiveness evidence for defined diagnostic groups from the Spine Patient Outcomes Research Trial showed good value for surgery compared with nonoperative care during 4 years. They also found that patients with predominant leg pain improved significantly more with surgery than did patients with predominant low back pain. However, patients with predominant low back pain still improved significantly more with surgery than with nonoperative treatment [41]. Patients often will have residual back pain at some point after surgical intervention. Once the patient is cleared by the operating spine surgeon, a lumbar core stabilization exercise program that emphasizes general core strength, postural education, hip girdle flexibility and strength, and cardiovascular reconditioning is important postoperatively.

Two key controversies in the surgical management of lumbar spinal stenosis are the appropriate role for a concomitant arthrodesis (lumbar fusion) and the utility of instrumentation. A comprehensive multipart systematic review by Resnick and colleagues [42,43] concluded that the literature consistently supports the addition of arthrodesis, particularly posterior lumbar fusion, to decompression surgery only in patients with lumbar spinal stenosis secondary to spondylolisthesis.

Potential Disease Complications

The natural history of lumbar spinal stenosis is not well understood, but existing literature seems to indicate that most

cases do not lead to significant deterioration. Johnsson and coworkers [44] examined the symptomatic and functional outcomes of 19 patients with moderate stenosis who did not undergo surgery. Average follow-up was 31 months, at which time 26% were worse, 32% unchanged, and 42% improved. Another study by Johnsson and colleagues [45] observed 32 patients with spinal stenosis who did not receive treatment, 75% of whom had neurogenic claudication. At a mean follow-up period of 49 months, 70% were unchanged, 15% were worse, and 15% were better. In patients with worsening symptomatic stenosis, there may be a progressive increase in back or leg pain and a decrease in walking tolerance. Severe stenosis may lead to a neurogenic bladder, especially in patients with narrowed dural sac anteroposterior diameter. Cauda equina syndrome is a rare but serious complication, in which case emergent surgical decompression is generally required.

Potential Treatment Complications

Exacerbation of symptoms is possible, particularly with functional restoration programs that may attempt to condition patients to painful activities through safe repetition of pain-inducing motions. In addition, patients with significant comorbidities, such as cardiopulmonary disease, are at risk for activity-induced adverse events. Complications from medication use include liver toxicity with acetaminophen; gastritis, gastrointestinal bleeds, renal toxicity, and platelet inhibition with nonsteroidal anti-inflammatory drugs; increased risk of cardiovascular events with some cyclooxygenase 2 inhibitors; nausea and lowering of seizure threshold with tramadol; anticholinergic effects including dry mouth and urinary retention with tricyclic antidepressants; sedation, ataxia, and other cognitive side effects with anticonvulsants (although gabapentin and pregabalin are relatively safe); and sedation, constipation, urinary retention, tolerance, and central pain sensitization with opioids. Adverse gastrointestinal events related to nonsteroidal anti-inflammatory drugs can be minimized with the use of a cyclooxygenase 2 inhibitor or concomitant use of a gastroprotective agent, such as a proton pump inhibitor or H₂ blocker [46].

Quantified data on complications associated with nonsurgical interventional procedures, including epidural steroid injections, are limited. A retrospective study of 207 patients receiving transforaminal epidural steroid injections [47] reported the following adverse events: transient nonpositional headaches that resolved within 24 hours (3.1%), increased back pain (2.4%), facial flushing (1.2%), increased leg pain (0.6%), vasovagal reaction (0.3%), increased blood glucose concentration in an insulin-dependent diabetic (0.3%), and intraoperative hypertension (0.3%). Other potential complications are infection at the injection site, dural puncture potentially with associated spinal headache, chemical or infectious meningitis, epidural hematoma, intravascular penetration, anaphylaxis, and nerve root or spinal cord injury leading to paresis or paralysis [48].

Complications of decompressive surgery include infection (0.5% to 3%), epidural hematoma, vascular injury (0.02%), thromboembolism including pulmonary embolism (0.5%), dural tears (<1% to 15%), nerve root injury, postsurgical spinal instability, nonunion or hardware failure,

adjacent segment degeneration, recurrence of symptoms (10% to 15%), and death (0.35% to 2%) [49].

CHAPTER 51

Sacroiliac Joint Dysfunction

Zacharia Isaac, MD

Richard Feeney, DO

Synonyms

Sacroiliac joint syndrome
Sacroiliac joint pain
Sacroiliac joint injury
Sacroiliac subluxation
Sacroiliac joint instability
Sacroiliac joint ankylosis
Sacroiliac joint sprain and strain

ICD-9 Codes

724.6 Disorders of sacrum
846.1 Sprain and strain of sacroiliac ligament
846.8 Sprain and strain of sacroiliac region

ICD-10 Code

S33.6 Sprain of sacroiliac joint or ligament
Add seventh character to S33 for episode of care (A—initial encounter, D—subsequent encounter, S—sequela)

Definition

Although chronic low back pain is more commonly attributed to the lumbar intervertebral disc and the zygapophyseal joints, the sacroiliac joint remains a significant cause of low back and buttock pain. However, diagnosis and treatment of sacroiliac joint dysfunction are a clinical challenge. The diagnosis of sacroiliac dysfunction should be considered only after careful exclusion of many separate distinct pathologic entities. Sacral fractures, sacroiliac joint inflammation (such as is seen with various seronegative spondyloarthropathies), metastatic disease, and even infectious seeding of the sacroiliac joint are but a few known pathologic conditions that deserve investigation. Imaging studies are often unhelpful and nonspecific in sacroiliac joint dysfunction.

In addition, because of its redundant and variable innervation, sacroiliac joint dysfunction can be manifested with a variable pain referral pattern [1]. Thus, one must consider pathologic changes of neighboring structures sharing pain referral regions with the sacroiliac joint before deciding on the diagnosis of sacroiliac joint dysfunction.

The prevalence of sacroiliac joint dysfunction in those with low back pain complaints is thought to be between 10% and 25%, although during pregnancy the sacroiliac joint is the source of low back or posterior pelvic pain in 20% to 80% of cases [2]. As such, sacroiliac joint dysfunction may be more common in women than in men, and various studies demonstrate a female-to-male ratio of approximately 3:1 to 4:1 [1,3,4]. Moreover, in comparing causes of chronic low back pain, female gender and low body mass index are associated with sacroiliac joint dysfunction [5].

Adjoining the axial and appendicular skeleton, the sacroiliac joint occupies a critical biomechanical position (Fig. 51.1). It is thought that joint dysfunction occurs with structural change to the joint or positional changes relative to the sacrum and pelvis [6]. One can appreciate such changes in pregnancy-related instability [7] or with joint misalignment in adolescents, both of which are known sources of sacroiliac joint pain and dysfunction [8]. Pain associated with changes in position or the joint anatomy itself may be mediated by intra-articular, capsular, and ligamentous structures.

The sacroiliac joints are the bilateral weight-bearing joints that connect the articular surface of the sacrum with the ilium. The anterior and inferior third of the joint is synovial; the remainder of the joint space is syndesmotic. The sacroiliac joint is bordered on its ventral and superior edges by the ventral sacroiliac ligament and on its dorsal and inferior surfaces by the interosseous and dorsal sacroiliac ligaments. The articular capsule of the sacroiliac joint is thin and stabilized anteriorly by the ventral sacroiliac ligament. The strong extracapsular fibers of the dorsal sacroiliac and interosseous ligaments contribute principally to the stability of the joint. Further anchoring of the sacroiliac joint is conferred by the sacrotuberous and sacrospinous ligaments, which provide additional connections between the pelvis and sacrum. Innervation of the sacroiliac joint remains an area of active study, and differing descriptions of sacroiliac joint innervation exist. Anatomic studies have described innervation primarily through dorsal rami of spinal nerve roots

FIGURE 51.1 Sacroiliac joint and ligamentous structures. (From Huntoon M, Benzon H, Nauroze S. *Spinal Injections and Peripheral Nerve Blocks*. Philadelphia, WB Saunders, 2012. *Interventional and Neuromodulatory Techniques for Pain Management*, vol 4.)

L5-S4. However, recent studies indicate that the sacroiliac joint receives its innervation from the ventral rami of L4 and L5, the superior gluteal nerve, and the dorsal rami of L5, S1, and S2 or that it is almost exclusively derived from the sacral dorsal rami [9]. Yet others suggest that dorsal innervation to the sacroiliac joint is from the L5 dorsal ramus and the S1-S3 lateral branches, whereas the ventral innervation derives from the ventral rami of L4 and L5 [10].

The sacroiliac joint undergoes changes throughout life that affect the biomechanics of the joint. During childhood and adolescence, the joint is more mobile, absorbing forces throughout the gait cycle. With normal aging, the joints develop uneven opposing surfaces, and the joints are thought to gradually fuse in later years [11]. Movements around the sacroiliac joints are small in magnitude yet complex in nature. As body weight is transmitted downward through the first sacral vertebra, the sacrum is pushed downward and forward, causing its lower end to rotate upward and backward. Although there are no muscles that directly control movements around the joint, imbalance of the musculature surrounding the sacroiliac joint can affect stresses through the joint. Muscles anterior to the sacroiliac joint, including

the psoas and iliacus, can influence movement of the sacrum [12]. Weakness in posterior muscles, such as the gluteus maximus and medius, can affect pelvic posture during weight bearing, thereby altering stresses through the joint.

Symptoms

By far the most common presenting symptom of sacroiliac joint dysfunction is low back and gluteal pain, which can be indolent and refractory to traditional interventions and therapies. Pain referral from sacroiliac joint dysfunction is not limited to the lumbosacral region or buttocks, however. Presenting complaints often include pain that is aggravated by prolonged standing, asymmetric weight bearing, or stair climbing. Pain can also stem from running, large strides, or extreme postures [13]. Because of the complex and extensive innervation of the sacroiliac joint as detailed before, dysfunction within the joint may be manifested with pain localizing to several rather removed regions, such as the thigh, groin, and leg. Sacroiliac joint dysfunction does not cause pain by neural compression. However, because of the anatomic proximity of spinal nerve roots to the lumbar and sacral plexuses, pain

referral patterns can mimic a variety of neurologic pathologic processes. In a retrospective study of 50 patients with positive diagnostic response to fluoroscopically guided sacroiliac joint injection, investigators sought to characterize the most common presenting symptoms experienced by the cohort. The most common symptoms were buttock pain (94%), lower lumbar pain (72%), and lower extremity pain (50%). Pain in the distal leg and pain in the foot were also reported, as was low abdominal pain and groin pain [1]. Interestingly, the sacroiliac joint is recognized as the most likely source of low back pain after lumbar fusion [14].

Physical Examination

A thorough assessment of the low back, hips, and pelvis, including musculoskeletal and neurologic testing, is essential in isolating back pain caused by sacroiliac joint dysfunction and to exclude other common diagnoses. Examination should include measurement of leg length and assessment of pelvic symmetry by inspection of the posterior superior iliac spine, anterior superior iliac spine, gluteal folds, pubic tubercles, ischial tuberosities, and medial malleoli. The sacral sulcus is palpated and inspected with the patient prone, and any muscle atrophy in the gluteal muscles or distal extremity is noted. Atrophy in the limb implicates a lumbar radiculopathy more than sacroiliac joint syndrome. Palpation of the bony sacrum, subcutaneous tissues, muscles, and ligaments also helps to complete the examination.

Provocative tests have long been used by clinicians to differentiate sacroiliac joint–derived back pain from other regional pain generators. However, repeated clinical studies have suggested that when they are considered separately, the most commonly used provocative tests have low specificity for sacroiliac dysfunction [15–18]. One possible explanation for this is poor inter-rater reliability. Others suggest that both the minimal range of motion around the joints and the difficulty in simulating physiologic stresses through the joints make it more likely that provocative tests will elicit pain from surrounding structures [13]. Such structures include the lumbar intervertebral disc, zygapophyseal joint, and hip joint. Several investigators have shown that in the diagnosis of sacroiliac joint disease, a multitest regimen is more clinically useful than any isolated finding. Recent research suggests that three or more positive findings on provocative tests are 82% to 85% sensitive and 57% to 79% specific for sacroiliac joint disease [18,19]. There is some evidence, in fact, that patients with low back pain who point to the posterior superior iliac spine or within 2 cm from this landmark are more likely to respond to periarticular sacroiliac joint blockade, thus making the patient's ability to pinpoint the pain a potentially useful tool.

Provocative Tests

Gaenslen Test

With the patient supine, lying close to the edge of the examination table with the buttock of the tested side over the edge of the table, the patient's leg is dropped off the table such that the thigh and hip are in hyperextension. The contralateral knee is then maximally flexed. Pain or discomfort with this maneuver suggests sacroiliac joint disease, although a false-positive result can be seen in patients with an L2-L4

FIGURE 51.2 Gaenslen test. The patient lies supine and moves toward the edge of the examination table. The examiner presses on the contralateral anterior superior iliac spine and the ipsilateral thigh. The result is considered positive if the test reproduces familiar gluteal pain.

nerve root lesion [20], spondylolisthesis, sacral fractures, lumbar compression fractures, or spinal stenosis (Fig. 51.2).

Patrick Test (also called FABER Test)

With the patient supine on a level surface, the thigh is flexed and the ankle placed above the patella of the opposite extended leg. Downward pressure is applied simultaneously to the flexed knee and the opposite anterior superior iliac spine as the ankle maintains its position above the knee. Pain or discomfort in the gluteal region reflects sacroiliac disease; pain in the groin or thigh may be suggestive of hip disease (Fig. 51.3).

Gillet Test

With the patient standing, the examiner palpates both the spinous process of the second sacral vertebra and the posterior superior iliac spine of the affected side. The patient is asked to maximally flex the hip on the involved side. A positive test result is indicated by a reproduction of pain and the failure of the palpated posterior superior iliac spine to move inferiorly in relation to the second sacral vertebra [2].

POSH Test (Posterior Shear Test)

With the patient supine, the examiner flexes the hip of the involved side to 90 degrees and adducts the thigh toward midline, providing axial pressure along the femur, directed into the table. This maneuver produces a shear force across the sacroiliac joint and reproduces pain in a symptomatic patient [2].

FIGURE 51.3 FABER (flexion, abduction, external rotation), also known as Patrick test. The patient's thigh is put into position while the examiner presses on the contralateral anterior superior iliac spine and ipsilateral thigh. The test result is considered positive if familiar gluteal pain is produced.

REAB Test (Resisted Abduction)

With the patient supine, the hip of the involved side is placed in 30 degrees of abduction with the knee extended. The patient is asked to provide an isometric abduction contraction while the examiner resists at the lateral ankle. Reproduction of pain in the region of the sacroiliac joint is a positive test result. The test is thought to stress the cephalad aspect of the joint [2].

Distraction Test (also called the Gapping Test)

With the patient supine, pressure is applied downward and laterally to the bilateral anterior superior iliac spines. This maneuver stretches the ventral sacroiliac ligaments and joint capsule while placing pressure on the dorsal sacroiliac ligaments.

Compression Test

With the patient lying in the lateral recumbent position, the examiner stands behind the patient and applies pressure downward on the uppermost iliac crest, compressing the pelvis. This stretches the dorsal sacroiliac ligaments and compresses the ventral sacroiliac ligaments.

Yeoman Test

With the patient positioned prone, the knee is flexed to approximately 90 degrees and the hip is extended by the examiner. The sacroiliac joint ipsilateral to the extended hip is being tested. Reproduction of familiar gluteal or pelvic pain is considered a positive test result (Fig. 51.4).

Pressure over the Sacral Sulcus

Application of pressure to the gluteal region causing familiar gluteal pain can be suggestive of sacroiliac joint dysfunction. This is commonly seen and is a nonspecific finding; it is often seen in discogenic axial pain, radicular pain, sacral fractures, facet syndrome, and piriformis syndrome.

Active Straight-Leg Raise

While lying supine, the patient lifts the lower extremity, one at a time with the knee extended, approximately 20 cm above the horizontal surface. Pain over the posterior pelvic

FIGURE 51.4 Yeoman test. The patient is positioned prone and the ipsilateral hip is passively extended by the examiner while the knee is at a 90-degree angle. The test result is considered positive if familiar gluteal pain is provoked.

girdle on either side represents a positive test result suggestive of sacroiliac joint dysfunction. This test has been validated against a prior test of posterior pelvic pain after pregnancy, in which excessive motion at the sacroiliac joint is thought to play a role [21].

Functional Limitations

Patients with sacroiliac joint dysfunction can have a range of functional limitations. There can often be difficulty with sitting, standing, walking, lying, bending, lifting, or sustaining any one position. Thus, their ability to work certain jobs will be limited. These functional limitations can be mild or incapacitating. Known sequelae of chronic pain conditions, including sacroiliac joint dysfunction, are insomnia, depression, globalization of pain syndrome, psychological pain behavior, and symptom magnification. These sequelae can have additional or disproportionate associated functional limitations.

Diagnostic Studies

Sacroiliac joint dysfunction has no valid or reliable diagnostic imaging studies. The purpose of obtaining imaging is to evaluate for alternative diagnoses. Plain radiography can reveal osteologic causes of sacroiliac joint-mediated pain, such as infection and inflammatory or degenerative arthritis. Plain radiographic views, including Ferguson views and anteroposterior views, can help identify sacroiliac joint erosions. Bone scan and computed tomography can detect bone changes caused by entities such as fracture, infection, tumor, sacroiliac joint erosions, and arthritis. Magnetic resonance imaging can reveal these entities as well as show soft tissue disease and marrow changes in sacroiliitis with its associated erosions. Recently, ultrasound has emerged as a modality capable of not only detecting pathologic changes within posterior ligamentous structures of the sacroiliac joint but also providing guidance for accurate intra-articular needle placement for diagnostic or therapeutic purposes [22]. However, true sacroiliac joint dysfunction can often be seen in the presence of normal imaging, and thus it is often defined clinically.

Fluoroscopically guided diagnostic intra-articular injection of anesthetics is considered by some the “gold standard” for diagnosis of sacroiliac joint–derived low back pain [4,17,23,24]. However, numerous investigators have shown anesthetic leakage from the joint space after injection, and there is speculation that overlap to adjacent neural structures may yield erroneous diagnoses of sacroiliac dysfunction. A placebo effect and other nonspecific factors also can lead to improper diagnosis. For these reasons, confirmatory studies should be performed after informed consent has been obtained and the patient is educated about the reasons for confirmatory studies. These confirmatory studies include a patient-blinded, placebo versus anesthetic injection and a variable-duration anesthetic time-dependent block. Despite these measures, reviews of the American Pain Society guidelines suggest that there is only fair to poor evidence for sacroiliac joint blocks to diagnose sacroiliac joint pain [25]. Recent evidence suggests that extracapsular structures, the dense ligamentous network comprising the sacroiliac joint complex, may be a principal cause of persistent pain. In a 2009 study by Dreyfuss and coworkers [10], anesthetic injections performed on asymptomatic individuals provided a strong case for comparative, multisite, multidepth lateral branch blocks as a diagnostic tool before radiofrequency neurotomy, a promising technique for refractory sacroiliac joint pain.

Differential Diagnosis

Discogenic low back pain
Lumbar radicular pain
Lumbar facet syndrome
Spondylolisthesis
Spinal stenosis
Bertolotti syndrome
Hip osteoarthritis
Piriformis syndrome
Sacral fractures
Multiple myeloma
Metastatic disease
Gout
Pseudogout
Seronegative spondyloarthropathy or sacroiliitis
Septic joint
Pelvic abscess
SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome
Osteochondritis dissecans
Osteitis condensans ilii

Treatment

Initial

Sacroiliac joint dysfunction is treated initially with relative rest and avoidance of provocative activities. Local modalities, such as ice and heat, or topical analgesics, such as lidocaine in patch form, can be applied for symptomatic relief. Manipulative therapy can alleviate pain and help with muscle spasms but does not change joint alignment significantly. Approximately only 2 degrees of rotation and 0.77 mm of translation occur with stress or manipulation [26,27].

Despite this, there is some evidence that the combination of high-velocity low-amplitude manipulation to both the sacroiliac joint and lumbar spine may provide improvements in pain and functional disability 1 month after intervention for those with sacroiliac dysfunction [28].

Commonly used pharmacologic interventions include acetaminophen, nonsteroidal anti-inflammatory medications, and muscle relaxants. Chronic use of nonsteroidal anti-inflammatory drugs should be avoided because of gastric, renal, and possibly cardiac side effects. Opiates in rare instances can be considered for short-term use but carry potential risks of sedation, constipation, physical dependence, and addiction. Patients with true sacroiliitis related to a seronegative spondyloarthropathy may be candidates for the use of biologic tumor necrosis factor- α inhibitor drugs or other disease-modifying agents.

Rehabilitation

Physical therapy is directed toward lumbar core muscle strength and hip girdle flexibility. Modalities such as ice massage, heat, electrical stimulation for the alleviation of pain or muscle spasm, sacroiliac joint mobilization techniques, and postural education exercises may be employed. Sacroiliac joint belts can be helpful and are worth an initial trial to address symptoms. Addressing hip girdle muscle strength, hip range of motion, tight iliotibial band, hip or knee osteoarthritis, trochanteric bursitis, leg length discrepancy, or pelvic obliquity can have adjunctive benefit. Given that most patients undergo rehabilitation for their low back pain without a specific diagnosis, it is difficult to determine whether physical therapy outcomes for sacroiliac joint dysfunction are any more or less effective than for other causes of low back pain. It stands to reason that exercise therapy aimed at improving strength, range of motion, and cardiovascular endurance can only benefit the patient overall and prevent the inherent trend toward deconditioning and activity avoidance behavior.

Procedures

Fluoroscopically guided intra-articular steroid injection can have therapeutic benefit. One study has suggested that up to two thirds of patients with sacroiliac joint dysfunction may attain significant pain relief [29], although the American Pain Society still regards the current evidence behind this therapy as poor [30]. Whenever possible, injection therapy should be complemented with a therapeutic exercise regimen.

Radiofrequency neurotomy has also been described as an effective treatment of sacroiliac joint dysfunction [31]. Interest and study have grown tremendously in this area of late. A recent meta-analysis endorses radiofrequency ablation as beneficial for sacroiliac joint pain for up to 6 months [32]. It is generally accepted that cooled rather than conventional or pulsed radiofrequency ablation is more effective at achieving pain relief [33,34]. Furthermore, recent evidence suggests that multisite, multidepth lateral branch blocks are physiologically effective at a rate of 70%, making this a valuable technique in diagnosis and in deciding to proceed with radiofrequency ablation to manage extra-articular sacroiliac joint pain [10].

Neuromodulatory therapies with an electrical stimulator implanted at the third sacral nerve root in a limited number of subjects with sacroiliac joint pain have also been effective in the management of refractory cases [35]. Prolotherapy has also been described for the treatment of sacroiliac joint dysfunction [16]. Well-designed randomized controlled trials are lacking for nearly all sacroiliac joint dysfunction treatments.

Surgery

Surgery is very rarely performed for sacroiliac joint dysfunction. A thorough workup is required before surgery with minimally invasive diagnostic anesthetization of the sacroiliac joint and to exclude discogenic, facet, radicular, and hip-mediated pain. Surgical intervention involves fusion of the sacroiliac joint with hardware.

Potential Disease Complications

Sacroiliac joint dysfunction, like other causes of chronic pain, can produce pain-related insomnia, depression, anxiety, globalization of pain, and disability. Older patients with gluteal pain should be evaluated for fracture or tumor, and younger patients should be evaluated for seronegative spondyloarthropathy. Degenerative causes of sacroiliac pain are more prevalent in women, whereas inflammatory causes predominate in men.

Potential Treatment Complications

Pharmacologic measures can have numerous side effects. Acetaminophen can be hepatotoxic in large doses. Nonsteroidal anti-inflammatory drug therapy is well known to be associated with gastrointestinal and renal side effects along with increased cardiac risk. Manipulation therapy or therapeutic exercise can increase pain in some patients. Intra-articular steroid injection can be associated with temporary increase in pain and local bleeding. Potential systemic steroid effects include increase in serum blood glucose concentration, hypertension, psychosis, and fluid retention. Local steroid injection can cause fatty atrophy, potential infection, and skin depigmentation.

Pelvis, Hip, and Thigh

CHAPTER 52

Adhesive Capsulitis of the Hip

Peter M. McIntosh, MD

Synonyms

Adhesive capsulitis of the hip
Frozen hip
Contracture of the hip joint
Ankylosis of the hip joint

ICD-9 Codes

718.45 Contracture of hip joint
718.55 Ankylosis of hip
719.55 Limitation of motion of hip
719.95 Hip joint disorder
726.0 Adhesive capsulitis of hip
726.90 Capsulitis NOS

ICD-10 Codes

M24.551 Contracture, right hip joint
M24.552 Contracture, left hip joint
M24.559 Contracture, unspecified hip joint
M24.651 Ankylosis, right hip
M24.652 Ankylosis, left hip
M24.659 Ankylosis, unspecified hip
M25.851 Joint disorder, right hip
M25.852 Joint disorder, left hip
M23.859 Joint disorder, unspecified hip
M76.891 Enthesopathies of right lower limb excluding foot

M76.892 Enthesopathies of left lower limb excluding foot

M76.899 Enthesopathies of unspecified lower limb excluding foot

M77.9 Enthesopathy or capsulitis, unspecified

Definition

Adhesive capsulitis of the hip joint is a condition of unknown etiology characterized by the gradual loss of passive and active hip motion, which is a result of retraction of the fibrous joint capsule.

Lequesne and colleagues [1] classified adhesive capsulitis into primary and secondary forms. Primary adhesive capsulitis is characterized by idiopathic, progressive, painful loss of both active and passive range of motion. Secondary adhesive capsulitis results from known intrinsic or extrinsic causes. Hannafin [2] reported that secondary adhesive capsulitis has a histopathologic appearance similar to that of primary adhesive capsulitis but can be associated with any one of multiple medical conditions (Table 52.1).

The hip joint is functionally and structurally complex, consisting of the femoral articulation, acetabulum, supporting soft tissue, muscles, and cartilaginous structures (Fig. 52.1). It is a multiaxial synovial ball-and-socket joint [3,4].

The femoral articulation forms roughly two thirds of a sphere, approximately 40% of which is covered by the acetabulum. Articular (hyaline) cartilage covers the femoral articulation except at the fovea capitis, a depression on the central surface.

The acetabulum is formed by fusion of the ilium, ischium, and pubis. It is hemispheric in shape and projects anterolaterally and inferiorly. The lunate surface is the articular portion, and the nonarticular portion constitutes the floor (acetabular

fossa). The acetabular fossa (covered by synovium) is continuous with the acetabular notch, which lies between the ends of the lunate surface. The acetabular fossa lies in the inferomedial portion, close to the ligamentum teres (round ligament), which attaches to the fovea capitis. The depth of the acetabulum is increased by the dense fibrocartilaginous labrum, which attaches to the rim of the acetabulum except at the acetabular notch.

The transverse ligament bridges the acetabular notch and in combination with the acetabular labrum forms a complete ring around the acetabulum. It converts the acetabular notch into a foramen through which the intra-articular vessels pass to supply the head of the femur [3,4].

The fibrous capsule of the hip joint attaches to the labrum to form a circular recess, which encloses the joint and most of the femoral neck (Fig. 52.1). Medially, it attaches to the base of the acetabulum and extends to the innominate. Inferiorly, it attaches to the transverse acetabular ligament. Laterally, it attaches to the femur anteriorly and extends along the intertrochanteric line and along the femoral neck

Table 52.1 Medical Conditions Associated with Adhesive Capsulitis

Thyroid dysfunction [15,37]
Recurrent minor trauma [12,38]
Diabetes mellitus (juvenile and adult onset) [39–41]
Female gender (>70%) [18]
Age (>40 years) [38]
Prolonged immobilization of a joint [23]
Coronary artery disease [25]
Autoimmune disorders [17]
After hip surgery
Intra-articular loose bodies
Osteoid osteoma
Synovial chondromatosis
Osteoarthritis
Dupuytren contracture
Elevated C-reactive protein level, positive HLA-B27/serum IgA level
Myocardial infarction
Pulmonary tuberculosis
Bronchitis
Stroke with hemiparesis

FIGURE 52.1 Hip joint. Normal anatomy and fibrous capsule.

posteriorly and inferiorly. The fibrous capsule is reinforced by the pubofemoral, ischiofemoral, and iliofemoral ligaments, which are considered thickening of the fibrous capsule and help to stabilize the hip joint. The capsular fiber consists of both superficial bands and deep bands. The deep circular bands from the iliofemoral ligament form the zona orbicularis, which divides the synovial cavity into medial and lateral recesses. The hip joint is dynamically stabilized by numerous muscles.

Neviaser introduced the term *adhesive capsulitis* and described pathologic changes in the synovium and subsynovium [5,6]. Evidence supports the hypothesis that the underlying pathologic process involves synovial inflammation with reactive capsular fibrosis, thus making adhesive capsulitis both an inflammatory and a fibrosing condition [2,5–9].

The histologic changes of adhesive capsulitis seen in the hip are similar to those in the shoulder. There is chronic inflammatory reaction in the capsule and synovium with subsequent adherence to the femoral neck [2,8,10,11]. Biopsy tissue shows evidence of edematous, fibrotic synovial tissue with partial or complete loss of synovial lining [2,12].

Many authors acknowledge that adhesive capsulitis is a relatively common clinical syndrome when it occurs in the shoulders (2% to 5% of the general population) but is infrequently described in other joints, such as the wrist, hip, and ankles [2,12–14].

Symptoms

The diagnosis of hip adhesive capsulitis is based on clinical findings of decreased passive and active range of motion in all planes of the hip joint, with no abnormal radiographic findings [5,15]. The patient may describe gradual onset of stiffness with hip movements, resulting in difficulty in crossing the leg or sitting in certain positions. Patients may describe difficulty with lower extremity dressing, such as putting on socks, or with hygiene, such as clipping of toenails.

Pain is usually a presenting symptom, especially with extreme external rotation or abduction, and is usually the reason for seeking medical evaluation. Gait difficulty may or may not be present, but it is usually not to the severity that a gait aid is required.

The diagnosis of hip adhesive capsulitis is rarely made, possibly because the hip joint can sustain range of motion loss without significant disability, whereas even a mild loss of motion in the shoulders can result in significant difficulty with performance of routine activities of daily living [12,13,15].

Physical Examination

Hip pain can be caused by different intra-articular and extra-articular structures. Differentiating the specific pathologic structures can be challenging, but it is critical for appropriate medical management. The history, physical examination, and adjuvant imaging are crucial in identifying the source of pain. In patients with adhesive capsulitis of the hip, the clinical examination findings may be minimal. The patient may or may not exhibit an antalgic gait pattern. The neuromuscular and neurovascular examination findings are usually unremarkable. The back examination is usually benign unless there is a concomitant spinal condition. Provocative maneuvers of the hip joint (i.e., Stinchfield and

FABERE tests) may generate nonspecific groin discomfort. The hallmark finding on physical examination is limitation of range of motion of the hip joint in all planes (flexion-extension, internal and external rotation, and abduction-adduction) [16].

Functional Limitations

Functional limitations may differ, depending on the severity of pain and range of motion deficits. Difficulty with activities of daily living are limited to the lower extremities. This can be manifested as difficulty with lower extremity dressing, such as donning or doffing pants, socks, or shoes. There is difficulty in crossing one leg over the other or sitting in a tailor's position. There may be difficulty in sleeping on one side or the other or standing with the hip externally rotated and abducted. There may be difficulty with prolonged sitting or driving a car, especially if a manual shift is used.

The onset of pain and inflammation causes reflex inhibition of the muscles around the joint, which can subsequently lead to loss of mobility and compensatory abnormal movement of the joint. If gait pattern is affected, recreational and vocational activities that require prolonged ambulation can be affected (i.e., golfing, tennis, or power walking for exercise). With time, there is resolution of pain, but residual range of motion deficits and limitation of function can remain. This persistent loss of mobility and dysfunction can lead to psychosocial issues, such as irritability, depression and anxiety, and disordered sleep patterns.

Diagnostic Studies

Laboratory studies are important in the initial evaluation of intra-articular hip abnormalities. They help assess for autoimmune and rheumatologic conditions. The results of laboratory studies, including blood cell counts, electrolyte values, chemistry panels, acute phase reactants, and rheumatologic screening studies (such as antinuclear antibodies, double-stranded DNA, rheumatoid factor, and HLA-B27 antibodies), are usually normal in patients with adhesive capsulitis of the hip [17,18].

Multiple imaging modalities are available to assess the pelvis and hip joint and surrounding soft tissues. Conventional radiography including anteroposterior views remains the initial imaging modality of choice in assessing patients with groin pain and dysfunction. These studies, however, are of limited value if there is internal derangement as the cause of hip pain because findings are typically normal in those circumstances. In hip adhesive capsulitis, results of these studies are usually normal except for possible diffuse osteopenia, most likely related to pain and decreased range of motion from underlying disease [19]. Griffiths and colleagues [12] reported on a series of patients who had adhesive capsulitis of the hips related to mild trauma or repetitive activity. In all of the patients, the conventional radiographs were unremarkable.

Bone scans can show increased uptake in the areas of osteopenia, but this is usually nonspecific. Focal accumulation of radionuclide reflects an alteration of balanced bone turnover due to changes in bone blood flow and can occur in several conditions [20].

Ultrasonography of the hip has been widely accepted as a useful diagnostic tool in patients with hip pain or limited range of motion. It allows evaluation of different anatomic and pathologic structures, such as joint recess, bursa, tendons, and muscles. It also allows evaluation of the osseous structures of the joint, ischial tuberosity, and greater trochanter. It is useful for guided procedures in the hip joint and periarticular soft tissue under direct visualization.

Ultrasonography has considerable advantages over computed tomography (CT) and magnetic resonance imaging (MRI); these include absence of radiation, good visualization of the joint cavity, quantification of soft tissue abnormalities, multiple joint scanning, and rapid side-to-side anatomic comparison. It also has relatively low cost, good patient compliance, and dynamic real-time study of multiple planes. Direct contact with the patient allows maneuvers that elicit symptoms to be evaluated while the study is being performed. Direct ultrasonographic visualization offers the possibility of guided procedures in the hip joint and periarticular soft tissues. The limited size and number of acoustic windows make detailed examination of some structures extremely difficult (i.e., femoral cartilage and hip capsule) [21]. It is not recommended for evaluation of hip adhesive capsulitis, in which there is retraction of the fibrous joint capsule with little or no fluid in the synovial space.

Supplemental imaging with CT or MRI is often used to further evaluate the pelvis and hip to rule out the presence of simple, nondisplaced avulsion to complex fractures and to assess for displacement, comminution, and locations of fragments. MRI is helpful in diagnosis of occult injuries and stress fractures and in the evaluation of the soft tissue and musculature of the pelvis and hip [19,22]. In adhesive capsulitis, CT scans are usually unremarkable and MRI shows capsular thickening with little or no fluid in the synovial space. If the clinical examination or a nonarthrographic CT or MRI study suggests a possible labral or intra-articular hip disease, direct magnetic resonance arthrography is performed [4,23].

Computed tomographic or magnetic resonance arthrography is the preferred examination for evaluation of the joint capsule, labrum, and articular cartilage. Intra-articular needle placement is confirmed under fluoroscopic guidance before 15 mL of 1:200 dilution of a gadolinium contrast agent and normal saline is injected into the joint [4]. Characteristic arthroscopic findings show a hip joint with low volume and loss of normal recesses, high intracapsular pressure, and a thick capsule (Figs. 52.2 and 52.3). There is usually reduction of intra-articular capacity of at least one third (<10 mL). In the series reported by Griffiths, the patients who underwent arthrography all had small-volume joint space (<8 mm) with a thick capsule and increased intra-articular pressure. Cone and associates [24] prospectively monitored intracapsular pressure during arthrographic evaluation of 10 patients with a painful hip prosthesis and radiographic evidence of loosening. Fifty percent of patients had restriction of the intra-articular space around the neck of the femoral component during arthroscopy. The contrast agent exhibited irregular appearance related to fibrosis and scarring of the capsule consistent with adhesive capsulitis. In those patients in whom an arthrographic abnormality was

FIGURE 52.2 Coronal image from magnetic resonance arthrography of the hip depicting a small-volume joint with tight joint capsule. Very small recesses of the hip joint, compatible with adhesive capsulitis, are demonstrated (arrows).

FIGURE 52.3 Coronal image from computed tomographic arthrography of the hip showing a small-volume joint with tight joint capsule. Areas of capsule rupture and extra-articular contrast material are demonstrated (arrowheads).

demonstrated, the intra-articular pressure was three times greater than normal.

Lequesne described seven patients with pain and limitation of movement in the hip, which he called idiopathic capsular constriction of the hip [1]. Plain radiographs were unremarkable, but hip arthrography suggested diminished articular volume. There was absence of filling of the normal recesses, and the joint had a smaller capacity (<10 mL) than a normal joint (14–20 mL) [12]. It has been said that if an experienced radiologist has difficulty entering the hip joint, adhesive capsulitis is often the cause [25].

Differential Diagnosis

Osteoarthritis of the hip joint (mild or early onset)
 Intra-articular loose bodies [32]
 Irritable hip syndrome (pain with little or no restriction of movement)
 Iliopsoas bursitis or tendinosis [4]
 Snapping hip syndrome (iliotibial band, iliopsoas tendon) [19]
 Greater trochanteric pain syndrome, trochanteric bursitis, iliotibial band tendinitis
 Ischiofemoral impingement [33]
 Femoroacetabular impingement [4,32]
 Osteitis pubis [19]
 Athletic pubalgia [19]
 Subtle hip fractures or stress fracture [4]
 Synovial osteochondromatosis
 Osteonecrosis of femoral head, avascular necrosis
 Labral disease [32]
 Osteoid osteoma [4]
 Neoplastic infiltration (whether it is metastatic disease or primary pelvic tumor)
 Pyogenic arthritis
 Hemochromatosis
 Spondyloarthropathy (ankylosing spondylitis) [34]
 Diffuse idiopathic skeletal hyperostosis
 Diabetic cheiroarthropathy (syndrome of limited joint mobility)
 Lumbar radiculopathy
 Tumoral calcinosis [35]
 Complex regional pain syndrome type [3,7,36]

Treatment

Treatment of adhesive capsulitis of the hip is controversial. There are many studies, in both the rheumatologic and orthopedic literature, regarding treatment of the shoulder, but not much is written about treatment of the hips. Neviasser [6–9] and Hannafin [2] have stressed the importance of an individualized program in the treatment of adhesive capsulitis of the shoulder based on the understanding of the clinical stages of the disease. The same should apply to the treatment of the hip. However, the diagnosis of hip capsulitis is rarely made, and when it is made, it is usually in the latter stages of the disease based on the time interval. It is exceedingly difficult to accurately quantify stages of the disease in the hip and therefore to correlate a treatment plan based on those stages.

Conservative treatment is recommended as the disease is self-limited. Spontaneous recovery time on average is approximately 13 months, with a range of 5 to 18 months [1,13,26,27]. Chard and Jenner [13] described three middle-aged patients with pain and stiffness in the hips. No evidence of systemic disease, local infection, or lumbar spine disease was found. Bone scan indicated increased uptake in two patients, but the results of hip arthrography and laboratory studies were normal. The patients recovered spontaneously after a few months.

Initial

Pain control can be achieved early with use of a nonsteroidal anti-inflammatory drug or oral steroid. If this is not beneficial, an analgesic can be tried. Activity modification is recommended to prevent irritation of the involved extremity. Physical modalities, such as ice massage, superficial moist

heat, transcutaneous nerve stimulation, interferential current therapy, and ultrasound, can be applied to help with pain control, swelling, and facilitation of physical therapy.

Rehabilitation

Physical therapy is the treatment of choice. The goal of treatment is primarily to restore mobility. Passive mobilization techniques are used to restore the optimal joint kinematics. These techniques can involve lateral translation, distraction, and anteroposterior glide. These maneuvers are done with the patient lying supine; the proximal thigh is palpated while the distal leg rests over the therapist's shoulder. The hip joint is distracted by the application of various forces parallel to the neck of the femur. Initially, the mobilization techniques should be gentle, keeping within the range of pain and reactive muscle spasm. The intensity of the exercises can be adjusted according to the irritability of the joint. Ultimately, stronger passive mobilization techniques may be required in which the joint is taken strongly and specifically to the physiologic limit of range to restore the full function of the hip joint. Stretching of the muscles around the hip joint, which tend to shorten, is important. Active mobilization techniques can be used to restore the optimal length of the erector spinae, quadratus lumborum, hamstrings, rectus femoris, iliopsoas, tensor fascia lata, hip adductors, piriformis, and deep external rotators of the hip. Strengthening of the core muscles, gluteals, and hip groups should be done to address strength, endurance, and timing of recruitment of those muscle groups. Miller and coworkers [28] reviewed the cases of 50 patients in a 10-year period and found that the majority of the patients regained motion with minimal residual deficits after conservative treatment with physical therapy and oral medications. In contrast, Shaffer and colleagues [29] reported that 50% of patients had pain or residual stiffness at 7 years after treatment. A specific home exercise program should be included with continued range of motion and flexibility exercises to prevent recurrence of hip adhesive capsulitis.

Procedures

Trigger point injection and intra-articular injection can be tried in recalcitrant cases not responding to conservative treatment. Trigger point injection can be helpful if there is associated muscle pain and spasm. Ultrasound-guided intra-articular injection with long-acting local anesthetic and corticosteroid has been used for pain control. Several randomized, placebo-controlled clinical trials have shown improvement of pain and hip disability after intra-articular injection of corticosteroids [30]. Fluoroscopically guided hip injection with contrast material to confirm intra-articular needle placement has been tried; alternatively, the hip joint can be injected during computed tomographic or magnetic resonance arthroscopy.

Manipulation under anesthesia is widely used for adhesive capsulitis of the shoulder but is rarely used in treatment of hip adhesive capsulitis. Luukkainen and associates [31] reported the case of a man with adhesive capsulitis of the hip treated successfully with manipulation under anesthesia and pressure dilation of the joint space by use of isotonic sodium chloride. The patient failed to respond to physical therapy, pharmacotherapy, and intra-articular hip injection with triamcinolone and lidocaine during a period of 3 years.

Surgical intervention may be deemed appropriate if conservative treatment fails and the symptoms persist for more than 15 months with interference of activities of daily living. Arthroscopic release is rarely performed. Mont and colleagues [27] described a patient with adhesive capsulitis who failed to respond to conservative treatment with oral medications, physical therapy, and injection trials. The patient underwent hip capsulectomy through an anterolateral approach 1 year after initial presentation. Continuous passive motion was used during the early postoperative period to maintain range of motion. The anterior approach was used to preserve femoral head vascularity and to limit postoperative bleeding.

Potential Disease Complications

Disease complications are usually related to the range of motion deficits and associated pain that accompanies hip adhesive capsulitis. Functional limitations, which vary from patient to patient, may develop. The loss of mobility at the hip joint can result in difficulties with prolonged stance, ambulation, and sitting. Sleeping postures can also be affected as the patient may not be able to sleep on either side.

Potential Treatment Complications

Pharmacotherapy can lead to treatment complications. Nonsteroidal anti-inflammatory drugs have well-documented side effects related to the gastrointestinal and renal systems. Oral steroids, if they are used at high doses for a prolonged time, can have systemic effects, such as easy bruising, weight gain, and osteoporosis. The pharmacotherapy complications can be minimized by closely observing the patient's ongoing medical issues, medication use, and response and potential for drug interactions.

Local injections can cause allergic reactions, infection at the injection site, hematoma, nerve damage, or tendon rupture with inadvertent injection into a nerve or tendon. Physical therapy can result in increased pain and dysfunction if it is not supervised by a well-trained, board-certified physical therapist. Manipulation under anesthesia can lead to an increased risk for chondrolysis and vascular and neurologic insult. Surgical complications are numerous and can include excessive blood loss and postsurgical infection. Compromise of the vascular supply to the femoral head can lead to avascular necrosis and the need for additional surgical procedures. Surgery can result in a cosmetically unpleasant incision around the hip.

CHAPTER 53

Hip Adductor Strain

Ricardo Colberg, MD

Synonyms

Groin strain
Hip adductor tendinitis or tendinopathy

ICD-9 Codes

719.45 Pain hip/pelvis
843 Sprains and strains of hip and thigh
843.8 Sprains and strains of other specified sites of hip and thigh
843.9 Sprains and strains of hip and thigh, unspecified site; hip NOS; thigh NOS

ICD-10 Codes

M25.551 Pain in right hip
M25.552 Pain in left hip
M25.559 Pain in unspecified hip
S76.211 Strain of adductor muscle, fascia and tendon of right thigh
S76.212 Strain of adductor muscle, fascia and tendon of left thigh
S76.219 Strain of adductor muscle, fascia and tendon of unspecified thigh
Add seventh character to S76 for episode of care

Definition

Hip adductor strain refers to an injury of the hip adductor muscles at the muscle belly, myotendinous junction, or tendon. It can be an acute or chronic injury. The hip adductor muscles include the adductor magnus, adductor brevis, adductor longus, pectineus, and gracilis muscles (Fig. 53.1). All of these muscles are innervated by the obturator nerve with the exception of the pectineus muscle, which is innervated by the femoral nerve. Their functions include hip adduction and hip flexion. Adductor strain is the most common cause of acute groin pain in athletes [1]. The adductor longus myotendinous junction is the most commonly injured site [2].

A prospective cohort study of the incidence of groin injuries during a 1-year period among Swedish male club soccer players reported that 8% of all injuries were in the groin area, and 52% of these were attributed to adductor muscle or tendon injuries [3]. A similar incidence was reported in a study of Norwegian female elite soccer players, in which 9% of all injuries were hip or groin strains; 83% of these were acute injuries and 17% were secondary to overuse [4]. For male ice hockey players of a single National Hockey League team, Tyler and colleagues [5] reported 3.2 strains per 1000 player-game exposures. Orchard and Seward [6] monitored all the injuries that occurred in the Australian Football League during 4 consecutive years. In total, more than 660 elite male athletes played 22 matches per season among 16 teams. There was an incidence of 3.3 groin strains per team per season, the second most common musculoskeletal injury after hamstring strain, and a recurrence rate of 21%. In addition, it was the third most prevalent injury after hamstring strain and anterior cruciate ligament tear, with 11.9 matches missed per team per season. A retrospective cohort study of 500 Australian Football League players indicated that 17% sustained a hip or groin injury during their junior years. Of these, 31% were secondary to a hip adductor strain or tear, and 17% were recurrent injuries [7]. Recurrence of hip adductor strains has been reported to be as high as 32% to 44% in ice hockey and Australian football athletes [5,8]. Adductor strains in elderly athletes older than 70 years occur at a slightly decreased incidence of 5% [9]. The incidence and prevalence of hip adductor strains in sedentary patients are unknown.

Athletes who participate in sports that require cutting and sudden change of direction (e.g., soccer, ice hockey, Australian-rules football) are at increased risk for this injury [10]. Adductor strains may also occur from an eccentric contraction of the adductor muscles opposing the abductor muscles, as may be seen with an explosive lateral propulsion in ice hockey [11]. Hip adductor strains have been attributed to low strength or flexibility of this muscle group [12]. There is usually poor conditioning of the trunk and lower extremities characterized by muscle imbalance among the pelvic stabilizing muscles, including the hip abductor and adductor muscles, as well as the core muscles and hip flexors [10]. In addition, poor technique and overuse are risk factors for adductor strains. In rare instances, sacroiliac dysfunction may be associated with adductor injuries [13].

Adductor strains may be classified according to functional limitation on physical examination or pathologic injury on radiographic imaging (Table 53.1). The functional classification

FIGURE 53.1 Hip adductor muscles.

Table 53.1 Functional and Radiographic Classifications

Grade	Functional Classification	Radiographic Classification
1	No loss or minimal loss of function or mobility	Inflammation at the injured site with no tear
2	Partial loss of strength and mobility	Partial tear of the adductor muscle or tendon
3	Complete loss of function	Full tear of the adductor muscle or tendon

may or may not directly correlate with the pathologic change of the tissue seen on radiographic imaging. If the injury is localized at the tendon or myotendinous junction, it may also be described as an adductor tendinitis, referring to an acute injury with active inflammatory process, or as an adductor tendinosis, referring to a chronic injury that is causing functional limitations and does not have an ongoing inflammatory reaction. Because it may be difficult to classify the presence of an inflammatory process, tendinopathy is used frequently to refer to an adductor tendon or myotendinous injury with partial or complete loss of function that may be acute or chronic.

Symptoms

Patients with hip adductor strains complain of sharp, stinging, or aching pain in the groin area that may radiate down to the anteromedial thigh. Symptoms are worse when they

adduct and flex the leg at the hip, such as when they move the outside leg into a car. They usually report tightness in the groin or anteromedial pelvic girdle region. In injuries involving a partial or complete tear of the muscle or tendon, they complain of soft tissue swelling and bruising in the medial thigh. Chronic injuries may hurt only during physical activity or sports participation.

Physical Examination

The patient presents with tenderness to palpation in the groin region, most commonly over the adductor longus tendon or myotendinous junction distal to the origin of the muscle at the anterior surface of the pubis between the crest and the symphysis. In severe injuries, a defect may be palpated in the muscle representing a tear in the muscle or tendon. There can be associated ecchymosis, swelling, and tenderness of the surrounding soft tissue. Antalgic gait may be noted with ambulation secondary to pain or dysfunction. Single-leg standing and squatting may reveal Trendelenburg sign, excessive hip internal or external rotation, or genu valgus or varus.

Pain or weakness of the hip adductor muscle may be elicited with active resisted hip adduction, hip adduction and flexion, and hip flexion. Groin pain may also be reproduced with passive forced hip abduction as well as with passive flexion, abduction, and external rotation of the hip (FABER test). The cross-over sign may be used to determine if the adductor strain is moderate to severe and likely to cause functional impairment. This maneuver consists of reproducing the typical groin pain while performing any of the provocative maneuvers mentioned before on the contralateral side (i.e., FABER test, active resisted hip adduction, or passive hip abduction). The squeeze test and the static resisted hip adduction test are specific examinations for hip adductor muscles. During the squeeze test, the patient is in the supine position with feet on the table, hips flexed to 45 degrees, and knees flexed to 90 degrees. The examiner places the fist between the knees and asks the patient to squeeze the fist by adducting the hips bilaterally. The resisted hip adduction test consists of laying the patient supine with legs straight, positioning each leg at 15 degrees of abduction, and bilaterally resisting active hip adduction.

Functional Limitations

Patients usually have difficulty with walking, running, doing pivot turns, going up and down stairs, and standing up from a sitting position and vice versa. As mentioned before, getting in and out of a car is particularly painful. Sexual intimacy is frequently avoided because of the proximity of the injury to the sexual organs and groin pain experienced as the adductor muscles contract to stabilize the pelvis.

Hip adductor strains present with significant functional limitations during sports participation and interfere with athletes' optimal performance. They may report difficulty with propulsion in the lateral direction due to the eccentric contraction of the hip adductor muscles attempting to decelerate the leg stride, tightness in the groin region despite stretching, and loss of maximal sprinting speed, among other complaints [10,14]. The biomechanics of movements involving the hip joint are consequently altered

as the athlete tries to avoid experiencing pain. If it is left uncorrected, this adaptation eventually leads to other injuries, such as contralateral hip adductor strain, osteitis pubis, and sports hernia.

Diagnostic Studies

Initial evaluation of groin pain should include plain films to rule out bone disease, such as hip osteoarthritis and neoplasm. Avulsion injuries of the symphysis pubis and inferior pubic ramus may also occur from chronic overuse and be manifested with adductor enthesopathy and osteitis pubis [15]. Magnetic resonance imaging is the optimal imaging tool to evaluate for groin and hip disease because it provides visualization of a large field and gives a three-dimensional view of the region with excellent soft tissue contrast resolution [16]. It is particularly effective for diagnosis of adductor muscle and tendon disease. Fat-saturated, fluid-sensitive magnetic resonance sequences in the axial-oblique and coronal planes are best for evaluating hip adductor strains [17] (Figs. 53.2 and 53.3). Magnetic resonance imaging also helps differentiate hip adductor injuries from other pelvic disease, such as acetabular labrum tears and osteitis pubis.

Ultrasound can be used to evaluate the adductor muscles under dynamic conditions, to compare the asymptomatic side, and specifically to image the area of maximal tenderness to detect tissue injury such as a partial or full tear [18] (Fig. 53.4). Ultrasound imaging can be as sensitive as magnetic resonance imaging in the acute setting; however, it has limited visualization in patients with large thighs and is less useful when prognostic indicators are required [19,20].

FIGURE 53.2 Coronal T2-weighted fat-suppressed magnetic resonance image of a right grade 1 adductor longus strain shows edema within the proximal tendon (arrow) and capsular injury to the pubic symphysis (arrowhead). (From Kavanagh EC, Koulouris G, Ford S, et al. MR imaging of groin pain in the athlete. *Semin Musculoskelet Radiol* 2006;10:197-207.)

FIGURE 53.3 Axial T2-weighted fat-saturated magnetic resonance image of a right grade 2 adductor brevis tear shows edema within the myotendinous region of the right adductor brevis (arrowheads). AL, left adductor longus; AB, left adductor brevis; AM, left adductor magnus. (From Brittenden J, Robinson P. Imaging of pelvic injuries in athletes. *Br J Radiol* 2005;78:457-468.)

FIGURE 53.4 Extended longitudinal ultrasound view of a grade 3 tear of the adductor longus at the myotendinous junction with associated muscle retraction. AL, adductor longus; P, pubic bone; proximal tendon (arrowheads); hematoma (asterisk). (From Brittenden J, Robinson P. Imaging of pelvic injuries in athletes. *Br J Radiol* 2005;78:457-468.)

Differential Diagnosis

- Athletic pubalgia or sports hernia
- Osteitis pubis
- Acetabular labrum tear
- Stress fracture of the femoral neck or pubic ramus
- Osteoarthritis
- Iliopsoas muscle strain
- Rectus femoris muscle strain
- Hip joint toxic synovitis
- Slipped capital femoral epiphysis
- Avascular necrosis of the femoral head
- Inguinal or femoral hernia
- Genitourinary causes, including testicular torsion
- Lymphadenopathy
- Obturator nerve entrapment
- Sacroiliac joint pain

Treatment

Initial

Hip adductor strains are managed initially with rest, ice, compression, elevation, and nonsteroidal anti-inflammatory drugs (NSAIDs) to decrease swelling and inflammation. Athletes with acute hip adductor strains are requested to stop competitive participation and training to avoid further injury. The initial treatment (first phase of rehabilitation) should focus on tissue protection using an elastic wrap or compression shorts, reducing the local inflammation with cryotherapy and NSAIDs, and minimizing excessive motion of the injured site as well as weight bearing as tolerated with crutches. This is especially important in the presence of an apophyseal injury or tendon tear. Other causes of groin pain should be ruled out (see [differential diagnosis](#)) before a comprehensive rehabilitation program is implemented.

Rehabilitation

When the acute inflammatory phase subsides, usually within 48 hours, the second phase of rehabilitation is started to facilitate tissue healing and proper collagen deposition. Any increased muscle tone guarding the injured site should be addressed with various therapeutic modalities, including soft tissue massage and gentle passive range of motion. The appropriate time to commence stretching is debated. Some experts suggest that stretching should be done early to promote proper lengthening of the injured tissue as it remodels. Others suggest that early stretching may expose the athlete to development of chronic tendinopathy and should not start until at least 4 days after the injury [14].

A gradual muscle strengthening program is implemented, initially focusing on gentle active range of motion of the hip and strengthening of adjacent regions including core stabilization exercises. After full pain-free passive range of motion is achieved, exercises specifically focusing on hip adductor strengthening are initiated, starting with static exercises and progressing to concentric exercises. Neuromuscular electrical stimulation may be used to assist proper muscle activation. Once the patient is pain free with concentric exercises, on average 2 to 4 weeks after the initial injury, eccentric exercises are started for strengthening of the injured site. In an example of a hip adductor eccentric exercise, the patient lies supine, places the feet together against a wall with knees at full extension and hips at 60 degrees of flexion, and then slowly opens the legs symmetrically into hip abduction. If pain is experienced during any of the stages of the gradual strengthening program, the specific painful activity should be modified or stopped until the exercises can be completed pain free.

The third phase of the rehabilitation program involving functional training can be implemented once strength and flexibility are recovered. Proprioceptive training and plyometric exercises on unbalanced surfaces are done to continue strengthening of the hip adductor muscles and to reeducate proper neuromuscular activation of the various pelvic stabilizing agonist and antagonist muscles. In addition, dynamic strengthening exercises that incorporate the entire body are started (e.g., cable cross-over pull while standing on unstable surface).

At some point between the second and third phase of rehabilitation, the patient may start doing straight-line

aerobic exercises, such as jogging or cycling, as long as muscle guarding is eliminated, there is no cross-over sign, and there is no pain experienced with the strengthening program. Distance, intensity, and time should be gradually increased as tolerated, ensuring that the athlete does not experience pain during or after the activity. Once the athlete tolerates straight-line running exercises at more than 75% of maximum performance, drills involving lateral movements and change of directions can be implemented. The last stage of functional training focuses on sports-specific exercises and drills that simulate actual playing.

The ultimate objective of the rehabilitation protocol is to improve the pelvic stability by balancing the strength between the opposing pelvic stabilizing muscles and, in the case of athletes, gradually return them to peak performance. Specifically, hip adductor muscles should have at least 80% of the strength of the ipsilateral hip abductor muscles before return to play [21]. The length of the rehabilitation program varies according to the severity of the injury and the athlete's demand on the pelvic stabilizing muscles for participation in his or her sport. Severe injuries may take up to 12 weeks for full recovery and return to play.

Procedures

Patients may have trigger points along the muscle belly of one or more of the adductor muscles. These may be managed by trigger point injections with a local anesthetic such as lidocaine. In chronic cases in which pain is severely interfering with the rehabilitation program, a corticosteroid injection under ultrasound guidance may be placed in the peritendinous area, avoiding direct injection into the adductor tendon. This will decrease any residual inflammatory reaction, reduce pain, and facilitate the athlete's completion of the rehabilitation protocol. In cases that have been recalcitrant to conservative measures, the patient may benefit from needling the tendon under ultrasound guidance to reactivate the tissue healing cascade [22]. A regenerative injectate such as platelet-rich plasma may be used; nonetheless, there is limited evidence of the benefits with use of these injectates [23,24]. Extracorporeal shock wave therapy may also be considered for recalcitrant cases [25].

Surgery

Referral to a sports medicine orthopedic surgeon should be considered with a significant avulsion fracture, complete adductor tendon tear, or chronic recalcitrant cases that failed the rehabilitation program. Depending on the chronicity of the injury, the patient may benefit from a partial or complete adductor tendon release. Most athletes who undergo adductor longus tenotomy return to competitive sports within 3 months [26].

Potential Disease Complications

Early diagnosis and treatment usually lead to successful outcomes and complete recovery. Continued activity or sports participation without proper rehabilitation frequently causes worsening pain, weakness, and functional limitations. Signs of mild hip adductor strains include recurrent tightness during or after activity with no relief from stretching

and a decrease in sports-specific performance. Mild injuries may become severe if they are not treated accordingly. In addition, the injured adductor muscle will cause pelvic instability and may lead to further injury of the suprapubic muscles or the contralateral hip adductor muscles.

Potential Treatment Complications

Early return to play may lead to recurrent hip adductor strains [27]. Management of a hip adductor strain with only rest or NSAIDs will provide symptom relief but will not address the original cause of the injury, which in most cases is attributed to poor conditioning and imbalance of the pelvic stabilizing muscles. Athletes who complete an active training program are more likely to have excellent outcomes and pain-free successful return to sports in the first 6 months as well as to maintain significant improvement in symptoms up to 12 years after the injury compared with athletes who undergo a physiotherapy program without an active strengthening program [28,29]. Inadequate rehabilitation may lead to chronic injury, especially if there is concomitant pelvic dysfunction that is left untreated.

One of the most frequently used treatments for the pain associated with tendinopathies is prescription-strength anti-inflammatory drugs such as NSAIDs, selective cyclooxygenase 2 inhibitors, and corticosteroid injections. However, these treatment options carry potential risks for complications. A study of the effect of ibuprofen over rat Achilles tendon cells showed increased activity of the collagen-degrading enzymes, suggesting a detrimental effect of ibuprofen on the mechanism for tendon healing [30]. In vitro and in vivo experiments showed that NS-398, a specific cyclooxygenase 2 inhibitor, inhibited the proliferation and maturation of differentiated myogenic precursor cells, suggesting a detrimental effect on skeletal muscle healing [31]. Studies of corticosteroid injections for lateral epicondylitis show positive short-term results but frequent relapses and no significant difference from placebo or physiotherapy in the long term [32,33]. In addition, corticosteroid injections have resulted in tendon rupture in several cases of Achilles tendinopathy [34]. Surgery also carries significant risks. In addition to the risk of infection or nerve injury seen with most surgeries, adductor longus tenotomy may leave patients with decreased hip adduction strength [26]. Patients should be educated on the corresponding risks versus benefits of the chosen treatment plan.

Definition

Femoral neuropathy is the focal injury of the femoral nerve causing various combinations of pain, weakness, and sensory loss in the anterior thigh. The exact incidence of femoral neuropathy is not clear. However, the most common etiology is iatrogenic followed by tumor-related injury [1]. Hemorrhage, most often due to anticoagulation therapy, also is common. Table 54.1 lists other possible causes of femoral neuropathy.

The femoral nerve arises from the anterior rami of the lumbar nerve roots 2, 3, and 4. After forming, the nerve

passes on the anterolateral border of the psoas muscle, between the psoas and iliacus muscles, down the posterior abdominal wall, and through the posterior pelvis until it emerges under the inguinal ligament lateral to the femoral artery (Fig. 54.1) [2–4]. The course continues down the anterior thigh, innervating the anterior thigh muscles. The sensory-only saphenous nerve branches off the femoral nerve distal to the inguinal ligament and courses through the thigh until the Hunter (subsartorial) canal, where the nerve dives deep. The femoral nerve innervates the psoas and iliacus muscles in the pelvis and the sartorius, pectineus, rectus femoris, vastus medialis, vastus lateralis, and vastus intermedius muscles in the anterior thigh. The femoral nerve provides sensory innervation to the anterior thigh. The saphenous nerve provides sensory innervation to the anterior patella, anteromedial leg, and medial foot (Fig. 54.2).

Symptoms

The symptoms depend on how acute the injury is and what caused the injury. A patient will often first complain of a dull, aching pain in the inguinal region, which may intensify within hours. Shortly thereafter, the patient may note difficulty with ambulation secondary to leg weakness. The patient may or may not complain of weakness in the hip or thigh but will often notice difficulty with functional activities, such as getting out of a chair and traversing stairs or inclines. Numbness over the anterior thigh and medial leg is common. The numbness may extend into the anteromedial leg and the medial aspect of the foot.

Physical Examination

The examination includes a complete neuromuscular evaluation of the low back, hips, and both lower limbs. This should include inspection for asymmetry or atrophy, manual muscle testing, muscle stretch reflexes, and sensory testing for light touch and pinprick.

In the case of femoral neuropathy, the clinician may see atrophy or asymmetry of the quadriceps muscles. Weakness of hip flexion or knee extension may be present. Strength testing may be limited because of pain. Quadriceps strength should be compared with adductor strength, which typically is normal. Palpation over the inguinal ligament may reveal a

fullness or exacerbate the patient's pain symptoms. There is often a decreased or loss of quadriceps reflex and decreased sensation to the anterior thigh and anterior and medial leg. The thigh and groin may be tender to palpation. Pain may be exacerbated with hip extension (Fig. 54.3) [2,3].

**FIGURE 54.2** Sensory innervation of the femoral nerve.**Functional Limitations**

Functional limitations due to femoral neuropathy are generally a result of weakness and vary according to the severity of the injury and the functional reserve of the patient. Individuals may have difficulty in getting up from a seated position and walking without falling. Inclines and stairs often magnify the limitations. Recreational and work-related activities are often affected, such as running, climbing, and jumping.

Diagnostic Studies

Electrodiagnostic studies (nerve conduction studies and electromyography) are the "gold standard" to confirm the presence of a femoral nerve injury. These should be performed no earlier than 3 to 4 weeks after the injury. Obviously, in cases of suspected hemorrhage, imaging studies should be done immediately. Imaging studies may include magnetic resonance imaging or computed tomography of the pelvis to look for a hemorrhage or a mass causing impingement [4–7]. Ultrasound has been found

FIGURE 54.3 Traction on the femoral nerve may be accomplished with hip and knee extension initially (A) and then gentle knee flexion (B).

to be a valuable tool in needle localization for femoral nerve blocks as well as in the identification of femoral nerve injury [8,9].

In terms of electrodiagnostic studies, nerve conduction studies of the femoral motor component are routinely used. Sensory conduction studies of the medial femoral cutaneous nerve can be useful in the localization of femoral neuropathy [10]. Saphenous nerve sensory evaluation is available but is often technically difficult and unreliable [3]. The needle electromyography should evaluate muscles innervated by the femoral, obturator, tibial, and peroneal nerves. The needle evaluation therefore should include evaluation of the iliopsoas, at least two of the four quadriceps femoris muscles, one or two adductor muscles, gluteus minimus, three muscles between the knee and the ankle, and paraspinal muscles. Electromyography should be performed to rule out other causes of neuropathic thigh pain, including upper and mid lumbar radiculopathy, polyradiculopathy, and plexopathy. Serial electromyographic studies may help with evaluation of the recovery process. High-resolution magnetic resonance neurography is useful in the evaluation of femoral neuropathy, providing insight into pathologic causes including compressive lesions, as can be found in retroperitoneal hemorrhage or cancer [11].

Differential Diagnosis

- Lumbar radiculopathy
- Lumbar polyradiculopathy
- Lumbar plexopathy
- Avascular necrosis of the femoral head
- Polymyalgia rheumatica

Treatment

Initial

Treatment of femoral neuropathy is focused on three separate areas: relief of symptoms, facilitation of nerve healing, and restoration of function. In acute cases in which hemorrhage or trauma is the cause, surgical intervention may be the initial treatment. This is also the case when the injury is due to a mass lesion, such as a tumor.

Acute, subacute, and chronic relief of the pain and numbness is attempted with modalities and medications. Ice may be helpful acutely, and heat may be helpful in the subacute stage. If an inflammatory component is suspected, nonsteroidal anti-inflammatory drugs may help both pain and inflammation. Alternatively, oral corticosteroids may be used. Narcotics are used when acetaminophen and nonsteroidal anti-inflammatory drugs do not control the pain. Antiseizure medications, such as carbamazepine and gabapentin, are also of benefit for the neuropathic pain in some individuals [12,13]. Transcutaneous electrical nerve stimulation may also help with pain control.

Facilitation of healing depends on the cause of the injury to the nerve. In the case of diabetes, improved blood glucose control may help recovery [14]. Injury due to impingement may be improved by removal of the mass. Too often, little can be done to facilitate healing. Nerves that have sustained a less severe injury (neurapraxia injury) often heal within hours to weeks once the irritant is removed. Nerves that have sustained a more serious injury (neurotmesis or axonotmesis) typically have a much longer healing course because of the time required for wallerian degeneration and regeneration. It is important to educate the patient about the potential for a prolonged (sometimes more than 1 year) course of healing. Also, it is important to counsel patients that healing may not be complete and that there may be permanent loss of strength and sensation as well as continued pain symptoms.

Rehabilitation

Once the damage has been stopped or reversed, the focus turns to improvement of hip flexion and knee extension strength by maximizing the function of the available neuromuscular components. This is accomplished with physical therapy instruction and a home exercise program. Improvement of strength in all lower extremity muscle groups is important. Aggressive strengthening should be limited in a nerve that is acutely injured because it may promote further injury and delay healing [15].

It is also essential to work on proper gait mechanics. The physical therapist can help the patient with gait training and gait aids to prevent falls and to improve energy use. Range of motion in all lower extremity joints should be addressed. Neuromuscular electrical stimulation may be of benefit in improving strength in some individuals.

Procedures

Procedures are not indicated for this disease process.

Surgery

In the case of femoral nerve injury due to impingement, mass lesion, or hemorrhage, surgery may be required to remove the pressure. Early surgical evacuation in patients with femoral nerve compression secondary to retroperitoneal hemorrhage can reduce the likelihood of prolonged neurologic impairment [16]. In the case of a penetrating injury to the femoral nerve, surgery to align the two ends of the nerve and to remove scar tissue may be required. Successful transfer of the obturator nerve to the femoral nerve has also been reported in cases in which the lesion of the femoral nerve is complete [17].

Potential Disease Complications

Potential complications include continued pain, numbness, and weakness despite treatment. In addition, the weakness in the hip and knee increases the risk for falls.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Narcotics have the potential for addiction and sedation. Carbamazepine can cause sedation and aplastic anemia. The patient taking carbamazepine should be evaluated with serial complete blood counts and checking of carbamazepine level. Gabapentin can cause sedation. The potential risks of surgical intervention include bleeding, infection, and adverse reaction to the anesthetic agent.

 M16.50 Post-traumatic osteoarthritis, unspecified hip
 M16.51 Post-traumatic osteoarthritis, right hip
 M16.52 Post-traumatic osteoarthritis, left hip

Definition

Hip osteoarthritis (OA, also called degenerative joint disease) is the most prevalent pathologic condition at the hip joint. The hip joint (femoroacetabular joint) is a ball-and-socket joint, with the femoral head situated within the concavity formed by the acetabulum and labrum. This anatomic arrangement allows movements in multiple planes, including flexion, extension, adduction, abduction, internal rotation, and external rotation. Significant mechanical forces (three to eight times body weight) [1,2] are exerted on the hip joint during weight-bearing activities such as walking, running,

jumping, and lifting. Additional stresses are created by recreational activities (e.g., impacts and falls during sports) and severe trauma (e.g., motor vehicle collisions). Hip trauma is significantly associated with unilateral but not bilateral hip OA, whereas obesity is associated with bilateral but not unilateral hip OA [3]. Occupational heavy lifting and frequent stair climbing seem to increase the risk of hip OA [4].

In a study of 2490 subjects aged 55 to 74 years, the prevalence of hip OA was 3.1%; 58% of hip OA cases were unilateral and 42% were bilateral [3]. The prevalence of hip OA is about 3% to 6% in the white population, but by contrast, it is far lower in Asian, black, and East Indian populations [5]. Total hip replacement in patients with hip OA is twice as common in women [6].

A central feature of hip OA is cartilage breakdown, thus compromising the femoroacetabular articulation. In addition to cartilage, other tissues affected by the disease process include subchondral bone, synovial fluid, ligaments, synovial membrane, joint capsule, and adjacent muscles. Eventually, the joint develops osteophytes (exostosis), joint space narrowing, bone sclerosis adjacent to the joint, and potentially even joint fusion (arthrosis). OA can be classified as either primary (idiopathic) or secondary [7]. The most common form of hip OA is primary [8], which represents the “wear and tear” degenerative changes that occur over time. Hip OA is considered secondary if a specific underlying cause can be identified, such as significant prior hip trauma, joint infection, or preexisting congenital or other deformities [7]. Among patients undergoing total hip replacement, the likelihood that the hip OA was primary (rather than secondary) is highest among white individuals (66%), followed by black subjects (54%), Hispanics (53%), and Asians (28%) [9]. Unlike rheumatoid arthritis, OA is relatively noninflammatory during most stages of the disease process. Symptomatic acetabular structural abnormalities can occur in patients with hip instability from classic developmental dysplasia or post-traumatic acetabular dysplasia as well as with retroversion of the acetabulum [10].

Symptoms

Groin pain is the classic manifesting symptom for hip OA. Other presenting symptoms of hip OA include hip pain, stiffness, and associated functional limitations. Many patients report “hip” pain when really they are referring to the superior lateral thigh region (e.g., greater trochanteric bursitis rather than hip joint disease). Hip joint pain typically presents as

groin pain, perhaps with some referred pain down toward (and even beyond) the medial knee. Questioning the patient about lumbosacral, sacroiliac, or coccyx pain may reveal that the “hip” symptoms are actually referred from the spine. Hip OA pain usually has an insidious onset, is worse with activity (particularly weight bearing and rotational loading of the joint), and is somewhat relieved with rest [7]. Advanced OA may be painful even at rest [7]. The physician should specifically ask about any constitutional symptoms that might suggest infection or malignant disease and also about any history of hip trauma [11] (recent or remote).

Physical Examination

Antalgic gait is characterized by a limp with decreased single-limb stance time on the painful limb, a shortened stride length for the contralateral limb, and an increased double support time.

Range of motion should be evaluated not only at both hip joints (in multiple planes) but also at the lumbosacral spine, knees, and ankles to more thoroughly evaluate the kinetic chain. The earliest sign of hip OA is loss of hip internal rotation [12,13]. Limping, groin pain, or limited hip internal rotation supports a diagnosis of a hip (rather than spine) disorder [14], but it still remains prudent also to perform a lumbosacral physical examination when lumbosacral pain generators are being considered. Whereas no one physical examination maneuver is diagnostic of hip OA or other form of intra-articular hip disease, assessment for painful range of motion about the hip, palpation, manual muscle testing, screening for radiculopathy and neuropathy, observation for systemic signs of OA, and performance of a provocative maneuver known as the Patrick test represent a reasonable evaluation. The Patrick test is performed by having the patient supine with the ipsilateral heel on the contralateral knee, thus forming the figure four position, also referred to by the acronym FABER (hip flexed, abducted, and externally rotated) maneuver (Fig. 55.1). The physician pushes the raised leg toward the table, producing groin pain that suggests intra-articular hip disease or back or buttock pain that suggests sacroiliac joint disease.

FIGURE 55.1 FABER maneuver (Patrick test). Pain produced in the groin suggests intra-articular disease, such as hip OA; pain produced in the back or buttock suggests sacroiliac disease.

Palpation of the tissues about the greater trochanteric region, proximal iliotibial bands, sacroiliac joints, gluteal muscles, underlying piriformis and obturator internus muscles, and ischial bursae may reveal pain generators other than the hip joint itself.

Weak hip girdle muscles may be due to pain or disuse, but radiculopathy and neuropathy can also be considered. Hip abductor weakness may be manifested with a Trendelenburg gait [13]. With hip OA, the remainder of the neurologic examination in the lower limbs is normal (e.g., muscle stretch reflexes and sensory testing).

On inspection of the fingers, hypertrophic degenerative changes (exostoses), such as Heberden nodes at the distal interphalangeal joints [12], are independent risk factors for hip OA [11]. Their presence thus increases the likelihood of similar findings at the hip joint.

Functional Limitations

Patients with hip OA often report functional limitations in weight-bearing activities such as walking, running, and climbing stairs. The hip range of motion restrictions may cause difficulties with activities such as donning or doffing socks and shoes, picking up clothing from the floor [15], and getting in and out of cars. Hip pain and weakness may necessitate use of the upper limbs to arise from a chair [15]. A careful history can elicit details of occupational, recreational, and other functional activities that the patient has decreased or ceased because of the hip OA.

Diagnostic Studies

Plain radiography is the primary diagnostic study for hip OA [16] (Fig. 55.2). The severity of radiographic hip OA findings can be categorized on the basis of the minimal joint space (MJS), defined as the shortest distance on the radiograph between the femoral head margin and the acetabular edge [15]. MJS is determined by four joint space measurements (medial, lateral, superior, and axial). Croft's MJS grades are 0 (MJS > 2.5 mm), 1 (MJS > 1.5 mm and ≤ 2.5 mm), and 2 (MJS ≤ 1.5 mm) [15]. MJS is predictive of hip pain, is strongly associated with other radiographic features of hip OA, and has a high inter-rater reliability [17]. Alternatively, the Kellgren-Lawrence grading system of hip OA is a scale of 0 to 5 that considers not only joint space narrowing but also three additional factors: presence of osteophytes, subchondral sclerosis, and subchondral cysts [15]. Both MJS and Kellgren-Lawrence grade are associated with clinical symptoms of hip OA [15].

Magnetic resonance imaging is generally not needed to diagnose hip OA, but it is superior to radiography or bone scan when the differential diagnosis includes avascular necrosis or hip labral tear [18]. Hip joint arthrography is also generally unnecessary for the diagnosis of hip OA but may help define labral tears. Diagnostic musculoskeletal ultrasound can assist in early detection of hip OA, can sometimes demonstrate gross evidence of bone and cartilage damage, can detect associated synovitis [19], and can detect concomitant iliopsoas bursitis [20]. Hip pain that is relieved through intra-articular diagnostic injection of local anesthetic (e.g., with ultrasound [21] or fluoroscopic guidance)

FIGURE 55.2 Radiograph demonstrating hip OA, including joint space narrowing, superior migration of the femur within the acetabulum, and subchondral sclerosis.

can help confirm that the patient's symptoms are arising from the hip joint and predicts a good surgical outcome with joint replacement [21]. Patients who fail to obtain adequate relief with image-guided anesthetic injection tend to have alternative pathologic processes at the spine (61%) or knee (16%) [21].

Electrodiagnostic studies should be considered when the differential diagnosis includes lumbosacral radiculopathy or peripheral nerve disease.

Differential Diagnosis

INTRA-ARTICULAR

- Avascular necrosis
- Protrusio acetabuli
- Hip labral (cartilage) tear
- Hip joint infection
- Acetabular fracture
- Inflammatory arthropathy, such as rheumatoid arthritis

EXTRA-ARTICULAR

- Femur fracture
- Trochanteric bursitis
- Iliotibial band tendinitis
- Iliopsoas bursitis
- Piriformis myofascial pain
- Snapping hip syndrome
- Muscle or tendon groin strain
- Lumbosacral radiculopathy
- Sacroiliac pain
- Coccydynia

Treatment

Initial

Patients with OA should be educated about their diagnosis, prognosis, and available treatments. Patients are encouraged to take an active role in managing their OA and maximizing their outcomes [22].

Weight loss is important because body weight is an independent risk factor for the development and progression of hip OA [23,24], although this relationship is less clearly established at the hip than at the knee [12]. Forces on the hip joint are roughly three to five times the patient's body weight during ambulation [2] and up to eight times body weight during jogging [1]. Loss of even modest amounts of excess body weight can significantly decrease lower extremity joint forces, OA progression, and related symptoms [23,24].

The initial medication of choice for OA is acetaminophen [25,26], at a maximum dose of 1000mg three times a day, depending on the presence or absence of hepatic dysfunction. Although OA is primarily considered a noninflammatory arthritis (at least in early stages), prescription of nonsteroidal anti-inflammatory drugs in addition to the acetaminophen can provide further analgesic benefit [12]. Diagnostic musculoskeletal ultrasound offers the clinician a practical way of quickly assessing for evidence of inflammation and thus potentially influencing medication selection. In appropriately selected patients, tramadol or more traditional opioid analgesics may also be used for pain relief and associated functional benefits [12].

Rehabilitation

The American College of Rheumatology guidelines for the medical management of hip and knee OA recommend exercise as an important component of treatment [24,25]. These guidelines recommend an exercise program consisting of range of motion, muscle strengthening, and aerobic conditioning by walking or aquatic therapy [24,25]. Water-based exercise for lower limb OA decreases pain and increases function in the short term and also at 1 year [27].

Stretching programs can address the range of motion restrictions in patients with hip OA, which are, in order of severity, extension, internal rotation, abduction, external rotation, adduction, and flexion [22]. Flexibility programs often begin with patients gently moving their joints through the available range of motion (to maintain range of motion) and then progress to regaining of lost range of motion. [12] Proper stretching should be sustained for at least 30 seconds while avoiding the sudden, jerky, or ballistic stretching that would be likely to exacerbate OA [12].

Muscle strengthening programs should address all planes of hip movement [22]. OA patients may begin with static strengthening exercises [12] to minimize joint movements that could exacerbate the OA symptoms [12]. Eventually, incorporation of dynamic exercises can maximize strength and function [12]. Patients with hip OA are often deconditioned, thus suggesting a role for aerobic exercises [22]. Because OA particularly affects the elderly, it is especially important to screen for cardiovascular or other precautions before an exercise program is begun. Many patients with hip OA may have difficulty tolerating high-impact aerobics,

such as jogging and stair climbing [22], so activities such as cycling (perhaps using a high-seat bike or recumbent bike, depending on the patient's symptoms) and aquatic exercises may be substituted. It is important to encourage ongoing exercise compliance [8,12].

There is little clinical scientific evidence supporting passive modalities (e.g., cryotherapy, thermotherapy, transcutaneous electrical nerve stimulation) for hip OA [22], although theoretically they may facilitate better tolerance of the active therapy program [12]. A recent literature review by a European multispecialty panel of experts concluded that massage, therapeutic ultrasound, electrotherapy, electromagnetic field, and low-level laser therapy cannot be recommended in hip OA [28].

Hip OA pain may be decreased by use of a cane in the contralateral hand [8,13], presumably by shifting the center of gravity medially, away from the involved hip. In cases of bilateral hip OA, the cane can be used contralateral to the more severely involved hip. A shoe lift can correct a leg length discrepancy [8] caused by hip joint space narrowing or superior migration of the femoral head within the acetabulum.

An occupational therapy evaluation of activities of daily living may identify difficulties with hand activities (e.g., due to hand OA) and difficulties with donning and doffing footwear (due to restricted hip range of motion). Adaptive equipment (e.g., reachers, sock donners, long-handled shoe horns, elastic shoelaces) may help maximize independence despite persistent physical impairments [12].

Procedures

Nonsurgical procedures for hip OA primarily include intra-articular injections with corticosteroids or viscosupplements.

Corticosteroid Injections

Although early OA is considered relatively noninflammatory, end-stage OA may have an inflammatory component [7], which may provide a basis for anti-inflammatory intra-articular injections with corticosteroids. It is difficult to obtain true intra-articular hip joint injection without fluoroscopy [8,12] or other image guidance such as ultrasound [21,29], particularly because the hip joint cannot be palpated and is adjacent to important neurovascular structures [29]. Also, OA can decrease the targeted joint space and osteophytes can obstruct needle entry [30]. A randomized controlled trial of fluoroscopically guided intra-articular hip joint injections has shown that compared with local anesthetic, corticosteroids decrease hip OA pain (at 3- and 12-week follow-up), improve hip range of motion in all directions, and significantly improve functional abilities [31]. Ultrasound-guided hip joint corticosteroid injection for hip OA has shown significant relief of pain during walking compared with saline injection [32]. Another prospective study of ultrasound-guided corticosteroid injection for hip OA showed that compared with baseline, there is significantly decreased walking pain at 1 and 3 months after injection [33] and 75% of the hips show decreased synovial hypertrophy at 1 and 3 months after injection [33]. Even in patients with advanced hip OA waiting for total hip replacement, image-guided intra-articular steroid injection can provide months of improved pain and function [34].

Despite the benefits shown in prospective, randomized controlled trials [31,32], it is notable that one retrospective study seems to show that combined injections of corticosteroid, contrast agent, and anesthetic before total hip arthroplasty may increase the risk of postoperative infection and surgical revision [35]. Despite the limitations of that study (inherent flaws of a retrospective review and data lacking statistical power to determine the role of the time interval between steroid injection and subsequent total hip arthroplasty) [35], the possibility of infection should be discussed with patients before corticosteroid injection. Hip joint injection under fluoroscopic guidance is shown in Figure 55.3.

Viscosupplementation Injections

True intra-articular placement is even more important with viscosupplementation than with corticosteroids because viscosupplements have high molecular weights and are unlikely to permeate to the joint capsule [30]. Thus, when it is available, image guidance with fluoroscopy [30] or ultrasonography seems prudent for viscosupplementation injections [35].

At the time of this writing, viscosupplements are approved by the Food and Drug Administration only for use at the knee. Some initial studies indicate that image-guided hip joint viscosupplementation injections are well tolerated, safe, and beneficial for hip OA [36]. Image-guided intra-articular hip viscosupplementation injections in symptomatic hip OA patients seems to effectively delay the need for total hip replacement surgery, thus decreasing OA-related financial costs and decreasing mortality related to total hip replacement [37]. A literature review concluded that viscosupplementation is as effective for hip OA as for knee

FIGURE 55.3 Fluoroscopic image showing intra-articular injection of contrast material (before corticosteroid), which can be seen spreading within the joint capsule along the proximal aspect of the femoral neck and also up into the space between the femoral head and the acetabulum. The image guidance helps ensure appropriate intra-articular placement of the injectate.

OA, appears to be a reasonable and safe alternative to oral nonsteroidal anti-inflammatories, and appears to work best in patients with milder radiographic findings of OA [38].

Surgery

Surgical treatment of hip OA (see Chapter 61) includes joint realignment (realignment osteotomy, such as for hip dysplasia [13]), joint fusion (arthrodesis), and, most commonly, joint replacement (arthroplasty) [26]. Hip joint arthroplasty can be categorized as either hemiarthroplasty (prosthetic replacement of the proximal femur while the acetabulum is left intact) or total hip arthroplasty (also called total hip replacement, with surgical replacement of both the acetabulum and the proximal femur) [26]. Hip hemiarthroplasty is often performed after proximal femur fractures, when the acetabulum is relatively intact. Conversely, in OA, there is usually degeneration of both the acetabulum and the femur; thus, the definitive surgery is to replace both of these through total hip arthroplasty. An arthroplasty can also be categorized on the basis of the specific prosthetic hardware used (e.g., unipolar or bipolar) and whether cement is used to hold the hardware in place [26]. Comparisons of the posterior and direct lateral surgical approaches for total hip arthroplasty show similar rates of postoperative dislocation (1% to 4%), postoperative Trendelenburg gait, and sciatic nerve injury [39].

Customized preoperative exercises are well tolerated even in patients with end-stage hip OA and improve early recovery of physical function after eventual total hip arthroplasty is performed [40]. Postoperative rehabilitation with physical therapy (and perhaps occupational therapy) generally includes therapeutic exercise, transfer training, gait training, and instruction in activities of daily living [41]. After total hip arthroplasty, early ambulation (even within the first 1 to 2 days postoperatively) [8] may maximize recovery and minimize complications such as deep venous thrombosis and symptomatic thromboembolism [41].

The patient is taught how to follow the weight-bearing status specified by the orthopedic surgeon [8], which depends on factors such as whether the prosthesis was cemented in place [41]. Many patients may safely bear weight as tolerated [41]. A cane or walker should be used until hip abductors are strong enough that the patient no longer limps during unassisted gait [8]. After a posterior approach total hip arthroplasty, prevention of hip dislocation often involves “hip precautions” (e.g., teaching the patient to carefully avoid positions of hip adduction, flexion, and internal rotation) [8]. Patients are taught to use elevated chair seats and elevated toilet seats and to avoid crossing the legs [8]. The recommended duration for hip precautions varies widely from 6 weeks to 6 months. Postoperative patients with a significant fall or sudden onset of pain should undergo radiography for evaluation of dislocation.

Prophylaxis against deep venous thrombosis and related venous thromboembolism may include early ambulation, intermittent pneumatic compression stockings, inferior vena cava filters, and pharmacologic methods (such as

unfractionated heparin, low-molecular-weight heparin, warfarin, or synthetic pentasaccharides) [41]. The optimal duration of thromboprophylaxis is not known, but a 4- to 6-week course has been suggested after total hip arthroplasty [41].

After the acute care hospital, total hip arthroplasty patients are discharged to either inpatient rehabilitation (acute or subacute) or directly home, depending on postoperative pain, functional status, and home environment [8,41].

Potential Disease Complications

Hip OA is a degenerative process characterized by gradual progressive worsening of femoroacetabular joint destruction and resultant symptoms. Hip OA can produce severe pain, stiffness, functional limitations, and associated compromise of quality of life. The decrease in mobility can subsequently result in weakness, osteoporosis, obesity, and cardiovascular deconditioning.

Potential Treatment Complications

Acetaminophen can cause hepatic side effects; nonsteroidal anti-inflammatory drugs are associated with gastrointestinal, renal, and cardiovascular risks. Tramadol can cause sedation and dizziness. Hip injections carry risks of infection and postprocedure exacerbation of symptoms. Hip replacement surgeries can be complicated by infection, nerve injury, dislocation, hardware loosening, deep venous thrombosis, and anesthesia-related side effects [41].

Definition

A hip labral tear is a tear of the fibrocartilaginous labrum that attaches to the periphery of the acetabulum. The acetabular labrum is a horseshoe-shaped fibrocartilaginous structure that attaches to the peripheral rim of the acetabulum, contacts the articular surface of the femoral head, and blends inferiorly with the transverse acetabular ligament. The labrum plays a major biomechanical role in hip joint stabilization and function. It increases the effective depth of the acetabulum, increasing static stability; it contributes to hydrostatic pressurization of the intra-articular space, joint lubrication, and load distribution; and it has proprioceptive and nociceptive nerve function [1].

The labrum can be divided into two distinct zones: the well-vascularized extra-articular side consisting of dense connective tissue; and the intra-articular side, which is largely avascular [2]. The chondrolabral junction is not uniform and has lower biomechanical strength at its anterosuperior acetabular attachment, which contributes to the higher incidence of labral tears in this area [3,4].

Hip injuries account for 3.1% to 8.4% of sports injuries, and labral tears are present in 22% to 55% of athletes with hip complaints [3,4]. Labral tears may be due to hip

instability, iliopsoas impingement, trauma, and osteoarthritis. Many labral tears are associated with a condition called femoroacetabular impingement (FAI) [5,6]. FAI is characterized by abnormal contact between the femoral head-neck junction and the acetabular rim caused by abnormal bone morphology. Ganz and colleagues [7] described two types of FAI: pincer and cam. Pincer-type FAI is due to excessive femoral head coverage by the acetabulum (Fig. 56.1), whereas cam-type FAI results from a decrease in the femoral head-neck offset distance (Fig. 56.1). Pincer-type FAI typically occurs in middle-aged women; cam-type FAI is more common in men in their fourth decade. Most cases of FAI have components of both pincer and cam types.

Whereas labral tears associated with both types of FAI tend to occur in the anterosuperior region, the bone abnormalities in cam-type and pincer-type FAI cause different patterns of labral tears. In pincer-type impingement, repeated contact between the femoral neck and the prominent anterior aspect of the acetabular rim leads to labral degeneration, tears, intra-substance ganglion formation, and, occasionally, labral ossification. In cam-type impingement, abnormal contact between the femoral head-neck junction and the acetabulum produces an outside-in abrasion of the acetabular cartilage and delamination between the acetabular cartilage and the adjacent labrum and subchondral bone [2]. The labral tears tend to occur on the articular rather than on the capsular surface. Although the bone patterns of FAI may differ, more commonly the osseous dysmorphism is a combined pattern.

Symptoms

Patients with labral tears complain of anterior groin pain made worse by long periods of standing, sitting, or walking. The pain can also be referred to the gluteal area or the trochanteric region. The onset of pain is usually insidious, with the patient often unable to recall a specific inciting event [2]. On occasion, the labral tear is due to trauma. Mechanical symptoms of clicking, locking, and instability are highly variable and not always indicative of intra-articular disease. A thorough history is critical, including inquiry about childhood diseases such as hip dysplasia, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis.

Physical Examination

The hip examination should begin by observing the patient's gait for antalgia. Palpation of the hip girdle may

FIGURE 56.1 A, Normal hip joint, which allows unrestricted hip motion. B, Pincer-type femoroacetabular impingement due to excessive coverage of the femoral head by the acetabulum. C, Cam-type femoroacetabular impingement secondary to a decreased femoral head-neck offset distance. (Modified from Tannast M, Siebenrock KA, Anderson SE. Femoroacetabular impingement: radiographic diagnosis—what the radiologist should know. *AJR Am J Roentgenol* 2007;188:1540-1552.)

reveal some tenderness in the groin region, but this is a nonspecific finding. Lumbar spine, hip, and knee range of motion should be assessed. Frequently, pain will be provoked with hip internal rotation during the hip range of motion assessment. A neurologic examination of the lower extremities should be completed, including evaluation of strength, sensation, and reflexes. The neurologic examination findings are typically normal. The most reliable test for FAI and a labral tear is the anterior hip impingement test, which is done by flexing the hip beyond 90 degrees, then adducting and internally rotating the hip (Fig. 56.2). The result is considered positive if the test elicits anterior groin pain [8]. A hip scouring maneuver, in which the hip is taken from an abducted and externally rotated position, through a flexed and neutral rotation position, and finally into adduction and internal rotation, may produce pain and possibly a “click” if a labral tear is present. Passive hip extension and external rotation may cause pain if a labral tear is present. This is commonly referred to as the posterior impingement test. Hip disease can also be provoked by placing the patient’s leg in a figure four position. This test is referred to as the Patrick test or FABER test because the hip is in a flexed, abducted, and externally rotated position. Intra-articular hip disease can also be elicited by a

FIGURE 56.2 The anterior impingement test involves flexing the patient’s hip to 90 degrees and adducting and internally rotating the hip. A positive test result is characterized by hip pain.

resisted straight-leg raise in the supine position. Although a detailed physical examination assists the clinician in determining that the patient’s pain is coming from the hip joint, it is nonspecific and cannot differentiate between the various causes of hip pain.

Functional Limitations

Although it is uncommon, a patient with a labral tear may have a limp or a Trendelenburg gait and rarely may require an assistive device to walk. A labral tear may also cause pain that limits activities, such as gymnastics or construction work, that involve repetitive hip loading, pivoting, and deep flexion.

Diagnostic Studies

Plain radiographs remain the mainstay in evaluating hip pain. A minimum of two radiographic views must be obtained. Proper patient positioning is critical to correctly assess the osseous anatomy. Commonly, an anteroposterior pelvis view and a cross-table (false profile) lateral view of the affected hip are used. Wenger and colleagues [9] reviewed hip radiographs of patients with labral tears and found that 87% had at least one bone abnormality consistent with FAI.

Pincer-type FAI may be due to generalized overcoverage of the femoral head from an excessively deep acetabulum or focal overcoverage related to acetabular retroversion. On the anteroposterior radiograph of the pelvis, the normal acetabulum should cover at least 75% of the femoral head. A deep acetabulum is present if the acetabular fossa or the femoral head projects medial to the ilioischial line. Focal acetabular retroversion is suggested by the cross-over sign, in which the cephalad portion of the anterior acetabular wall is lateral to the posterior acetabular wall. The cross-table lateral radiograph may demonstrate posteroinferior joint space narrowing.

Cam-type FAI can be evaluated with anteroposterior pelvis and cross-table lateral radiographs [10]. The primary radiologic finding of cam-type FAI is a decrease in the anterior or superior femoral head-neck offset distance, which causes the femoral head-neck junction to appear flattened or convex rather than concave. The asphericity of the femoral head-neck junction caused by cam-type FAI is commonly referred to as a pistol grip deformity (Fig. 56.3).

Magnetic resonance imaging is the preferred imaging modality for intra-articular hip disease as it provides high-resolution images of the acetabular labrum, hip joint cartilage, and joint space [2]. Magnetic resonance arthrography is the combination of magnetic resonance imaging with intra-articular injection of a gadolinium-based contrast agent and is the test of choice for evaluation of the acetabular labrum (Fig. 56.4) [11].

Differential Diagnosis

- Legg-Calvé-Perthes disease
- Slipped capital femoral epiphysis
- Hip dysplasia
- Hip septic arthritis, inflammatory arthritis, or osteoarthritis
- Hip malignant neoplasm
- Snapping hip syndrome
- Coxa profunda
- Protrusio acetabuli
- Avascular necrosis of femoral head
- Stress fracture of femoral neck
- Trochanteric bursitis
- Lumbar radiculopathy
- Inguinal or femoral hernia
- Iliopsoas tendinitis
- Psoas bursitis
- Peripheral nerve entrapment (e.g., genitofemoral nerve)
- Femoral artery thrombosis or dissection
- Femoral vein thrombosis

FIGURE 56.3 Anteroposterior right hip radiograph in a patient with cam-type femoroacetabular impingement. The arrow is pointing to the cam lesion. This femoral head-neck configuration is commonly referred to as a pistol grip deformity.

FIGURE 56.4 Sagittal T2-weighted magnetic resonance arthrogram of the hip. The arrow is pointing to a labral tear.

Treatment

Initial

The initial treatment of labral tears should be conservative and may include local application of physical modalities, mild oral analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs, and rehabilitation. If the patient's symptoms persist despite these measures, an intra-articular

corticosteroid injection could be considered [12]. Patients should be instructed to avoid aggravating activities.

Rehabilitation

The rehabilitation program for acetabular labral tears should progress through three phases. The first phase should focus on pain reduction through physical modalities, activity modification, and mild analgesics. The patient should work on reestablishing full pain-free range of motion and perform static strengthening exercises of the hip girdle musculature. Core strengthening exercises should be introduced, and the patient should maintain aerobic fitness through pain-free forms of nonimpact aerobic conditioning exercises. Kinetic chain deficits should be identified and addressed. Proprioceptive exercises such as single-leg stance on a stable surface or double-leg stance on an unstable surface should be included in the program. The second phase of rehabilitation should gradually introduce nonpainful, dynamic hip girdle strengthening exercises and low- to moderate-impact aerobic conditioning. Core stability and proprioceptive exercises should be advanced according to the patient's tolerance during this phase of rehabilitation. The final rehabilitation phase should transition the patient to sports-specific exercises (or work-specific exercises if the patient is not an athlete) and a home exercise program to maintain hip girdle strength and flexibility, core stability, aerobic fitness, and neuromuscular coordination [12].

An appropriate postsurgical rehabilitation program is necessary to maximize the patient's recovery [13]. Immediately after surgery, measures should be taken to reduce the patient's discomfort, including oral medications and local physical modalities. Compression should be applied at regular intervals to reduce postoperative edema. Frequently, a postoperative brace is used for the first 1 to 2 weeks during waking hours to prevent hip flexion beyond 80 degrees. At night, the patient may be required to wear an immobilizing brace to prevent hip external rotation, which places excessive tension on the anterior capsular structures. Gentle passive hip range of motion and active knee and ankle range of motion should be initiated. For the first 2 weeks after surgery, the patient should avoid excessive hip flexion, internal rotation, and abduction. As the pain resolves, the patient can begin working on reestablishing full pain-free range of motion. This usually takes place approximately 2 to 4 weeks after surgery. At 4 weeks after surgery, stretching exercises of the hip girdle and thigh musculature can be initiated.

Isometric hip girdle and thigh muscle strengthening can begin immediately after surgery but should be performed in a pain-free manner. Progression to isotonic hip girdle strengthening can begin after 2 to 4 weeks, with a focus on the hip abductors. Weight-bearing strengthening exercises typically can begin approximately 4 to 6 weeks after surgery. Exercises should include transverse plane movements but should always be pain free.

Partial weight bearing is continued for the first 2 to 6 weeks postoperatively, depending on the type of surgery performed and the surgeon's preference. The patient is weaned off of crutches after that time is complete.

Functional rehabilitation exercises usually begin approximately 6 to 8 weeks after surgery. Aerobic conditioning can progress from a limited weight-bearing environment (e.g.,

pool), to nonimpact full weight bearing (e.g., elliptical machine), to walking and jogging. Most individuals are unable to progress to impact-type aerobic conditioning (e.g., running) and cutting or pivoting activities until 12 to 24 weeks after surgery. In general, manual laborers can return to unrestricted work approximately 12 to 24 weeks after surgery, whereas athletes can return to competitive sports after 12 to 32 weeks, depending on the type of surgery performed and their ability to progress through the rehabilitation program.

Procedures

Some patients with acetabular labral tears may benefit symptomatically from an intra-articular corticosteroid injection. Hip injections should be performed with image guidance, such as ultrasound or fluoroscopy, to ensure accurate placement of the injectate into the hip joint, to minimize potential complications, and to maximize the therapeutic efficacy of the injection. Hip injections are typically considered as a treatment option after the patient has failed to respond to other nonoperative measures, such as local physical modalities, medications, and rehabilitation. However, if the patient is in significant pain and cannot participate in a rehabilitation program because of the severity of the pain, an intra-articular corticosteroid injection could be considered early in treatment to reduce pain and to facilitate the rehabilitation program.

Surgery

Surgical treatment should be considered in patients who have failed to respond to nonoperative measures or have significant mechanical symptoms. Originally, hip labral tears were treated surgically with open labral débridement. More recently, the advent of hip arthroscopy has allowed access to the labrum with significantly less morbidity. Short-term good to excellent results have been achieved with arthroscopic labral débridement. However, most of these studies included subjects with additional hip disease (e.g., articular cartilage injury) and were performed before the recognition of FAI [14]. Recently, it has been suggested that the optimal surgical treatment of hip labral tears is to repair rather than to debride the labrum to restore normal labral function [8]. The most commonly used labral repair technique involves placement of simple stitches. Comparison studies between labral débridement and labral repair surgeries are lacking. Thus, future investigations are required to answer the question of which surgical technique results in the best clinical outcomes [14].

When surgically treating a labral tear, many surgeons advocate addressing bone dysmorphisms that cause FAI (e.g., acetabuloplasty for pincer-type FAI or femoroplasty for cam-type FAI). Although there is a recent trend toward addressing the bone abnormality, there is no definitive evidence that the clinical outcome achieved with combined treatment of the osseous abnormality and the labral tear will be more favorable than that provided by isolated treatment of the labral tear [2].

Potential Disease Complications

If left untreated, labral tears can cause pain, mechanical symptoms (e.g., snapping, popping, locking), functional

limitations, and potentially osteoarthritis. If the patient also has FAI, the morphologic abnormalities of the femoral head or acetabulum result in abnormal contact between the femoral neck or head and the acetabulum. This leads to damage of the labrum and underlying cartilage. Theoretically, continued abnormal contact results in further deterioration and wear of the cartilage, with eventual onset of arthritis [15].

Potential Treatment Complications

Most nonoperative treatments have limited risk. The patient could have an allergic reaction to a medication, experience medication side effects such as dyspepsia, or have a medication complication such as gastric ulceration. Potential complications of intra-articular injections include infection, allergic reaction, and injury to adjacent neurovascular structures.

Potential complications of hip arthroscopy are mostly related to patient position and surgical technique. Traction is required for hip arthroscopy, which can cause nerve injury. This type of injury is minimized by avoidance of excessive traction and use of a wide post in the perineum. Adequate portal placement is of paramount importance in hip arthroscopy; inappropriate portal placement can lead to neurovascular injury and inadequate joint visibility, which can lead to iatrogenic structural damage [8].

G57.92 Unspecified mononeuritis of left lower limb
G58.9 Mononeuropathy, unspecified
R20.9 Disturbance of skin sensation

Definition

Lateral femoral cutaneous neuropathy, commonly called meralgia paresthetica, is the focal injury of the lateral femoral cutaneous nerve causing pain and sensory loss in the lateral thigh of the affected individual. The incidence of lateral femoral cutaneous neuropathy in the general population is

4.3 per 10,000 person-years. In addition, van Slobbe and colleagues [1] found that this neuropathy is more common in patients with carpal tunnel syndrome.

The lateral femoral cutaneous nerve is a pure sensory nerve that receives fibers from lumbar nerve roots L2-L3 (Fig. 57.1; see also Fig. 54.1). After forming, the nerve passes through the psoas major muscle and around the pelvic brim to the lateral edge of the inguinal ligament, where it passes out of the pelvis in a tunnel created by the inguinal ligament and the anterior superior iliac spine [2–4]. A number of anatomic variations have described the exit of the lateral femoral cutaneous nerve from the pelvis [5]. Approximately 25% of the population has an anomalous course of the lateral femoral cutaneous nerve out of the pelvis [6]. Approximately 12 cm below the anterior superior iliac spine, the nerve splits into anterior and posterior branches. The nerve provides cutaneous sensory innervation to the lateral thigh. The size of the area innervated varies among individuals.

The nerve may be injured as a result of a number of causes, as outlined in Table 57.1. Lateral femoral cutaneous neuropathy is more commonly seen in overweight individuals because of compression of the nerve (due to abdominal girth) when the thigh is flexed in a seated position.

Symptoms

Patients typically complain of lateral thigh pain and numbness. The numbness may be described as tingling or a decrease in sensation. The pain is often burning in quality but may be sharp, dull, or aching. The patient may also complain of an itching sensation. In some instances, there will be a precipitating event, such as a long car ride in which the patient was seated for a prolonged period, putting stress on the nerve. This is especially true in individuals who wear the seat belt snugly. The patient should not complain of weakness in the lower extremities. The diagnosis requires a high index of suspicion by the evaluating clinician.

Physical Examination

Because the lateral femoral cutaneous nerve is purely sensory, the only finding typical of this condition is decreased

FIGURE 57.1 The lateral femoral cutaneous nerve is purely sensory and innervates the anterolateral thigh.

sensation, which should be limited to an area of variable diameter in the lateral thigh. In adult men, the clinician may also see an area on the lateral thigh in which the hair has rubbed off. Palpation over the anterior superior iliac spine may exacerbate symptoms.

The physical examination is also used to exclude other possible causes of pain and weakness of the hip, thigh, and

knee. A complete neuromuscular evaluation of the low back, the hips, and the entire lower extremities is needed. This examination should include inspection for asymmetry or atrophy, manual muscle testing, muscle stretch reflexes, and sensory testing for light touch and pinprick. In the case of lateral femoral cutaneous neuropathy, the clinician should not see muscle atrophy or asymmetry or weakness of lower extremities. Reflexes should remain intact, and sensory testing outside of the lateral thigh should reveal intact function.

Functional Limitations

Typically, there are no functional limitations because this injury is more an annoyance than truly disabling. No true weakness is seen, although prolonged standing and extension at the hip may exacerbate the pain and thus limit the patient in performing tasks such as standing and walking. The nerve may be further compressed and the symptoms exacerbated when the patient is seated, so long car or plane rides may be difficult. Similarly, individuals who are sedentary at work may experience painful symptoms that limit their ability to function.

Diagnostic Studies

History and physical examination are the most important diagnostic tools, and all other testing should be used as an extension of these. Electromyography is the primary diagnostic tool and should include lateral femoral cutaneous sensory nerve conduction studies and needle electromyography of the lower extremity [3,4]. Although routine lateral femoral cutaneous nerve conduction studies have standard normal values with which an individual's study result can be compared, it is generally recommended to do comparison studies on the unaffected side, as the studies are technically difficult [4,7–9]. The side-to-side amplitude ratio has been shown to be a better way to confirm the diagnosis [10]. Shin and colleagues [11] documented the utility of recording from two sites within the lateral femoral cutaneous dermatome. This technique facilitates use of a more realistic amplitude in the side-to-side comparison. Controversy exists in regard to the best site of stimulation of the lateral femoral cutaneous nerve. Classically, the stimulation electrode is placed 1 cm medial to the anterior superior iliac spine. Recently, a stimulation site of 4 cm distal to the anterior superior iliac spine has been suggested as a means to obtain a more reliable response [12]. The needle electromyography is done to rule out other pathologic processes, and the recording should be normal. Serial electromyographic studies may help with evaluation of the recovery process.

Somatosensory evoked potentials may also be used, but a study reported that sensory conduction studies are a more reliable method of evaluation of the lateral femoral cutaneous nerve [13]. High-resolution ultrasound has also been advocated for the assessment of lateral femoral cutaneous neuropathy and has been found to highly correlate with electrodiagnostic findings [14]. Once the diagnosis is made, magnetic resonance imaging or computed tomography of the pelvis may be required to look for a mass causing impingement.

Differential Diagnosis

Lumbar radiculopathy
Lumbar polyradiculopathy
Lumbar plexopathy
Lumbar facet syndrome
Retroperitoneal mass
Femoral neuropathy

Treatment

Initial

Treatment of lateral femoral cutaneous neuropathy is focused on symptom relief and facilitation of nerve healing.

Both early and late symptomatic relief of the pain and numbness is attempted with modalities and medications. If an inflammatory component is suspected, nonsteroidal anti-inflammatory drugs or corticosteroids may be used. Narcotics are used when acetaminophen and anti-inflammatory medications do not control the pain. Acting as membrane stabilizers, antiseizure medications, such as carbamazepine and gabapentin, are also of benefit in some individuals [15,16].

Facilitation of healing varies according to the cause of the injury to the nerve. For most individuals, this entails removal of the cause of the pressure over the anterior iliac region. The pressure may be caused by tight clothing, belts, seat belts, or excess weight. Elimination of the pressure may include weight loss or clothing adjustment. Nerves that have sustained a less serious (neurapraxic) injury often heal within hours to weeks once the irritant is removed. Nerves that have sustained a more severe injury (neurotmesis or axonotmesis) typically have a much longer healing course because of the time required for wallerian degeneration and regeneration. The use of anti-inflammatory medications may also be of benefit in the healing process.

Rehabilitation

Physical therapy may facilitate healing of the injured nerve. Gentle stretching of the anterior thigh and groin is indicated to prevent contracture of the hip flexor muscles. The application of hot packs or ultrasound often facilitates the stretching process. Ice may be helpful when the patient continues to have swelling and inflammation around the pelvic brim. In some individuals, a general conditioning program to help with weight loss may also be useful. A dietitian can assist the patient with weight loss. A skilled therapist may be able to use soft tissue mobilization to help free an impinged and inflamed nerve. Augmented soft tissue mobilization is one of several techniques that may be useful. Electrical stimulation and transcutaneous nerve stimulation may be helpful in reducing the perception of pain by the patient during therapy treatments. Transcutaneous electrical nerve stimulation can be used on a daily basis for pain control.

Procedures

When conservative treatment fails, injection of the nerve at or near the anterior superior iliac spine with steroids and

local anesthetic may be helpful (Fig. 57.2). If the steroid injection is helpful but short lasting, the nerve can be injected with phenol or other neurotoxic agents as a last resort.

Under sterile conditions, the pelvis is palpated and the anterior superior iliac spine and inguinal ligament are identified. A 25-gauge, 2-inch needle is placed perpendicular to the skin approximately 1 inch medial to the anterior superior iliac spine and inferior to the inguinal ligament. The needle is advanced into the soft tissue approximately 1 inch (this depends on the patient's size and amount of excess subcutaneous tissue). At times, paresthesias may be elicited, thereby verifying needle placement; however, it is important not to inject directly into the nerve. Once the area to be injected is located, inject a 5- to 10-mL solution of local anesthetic and steroid (e.g., 2.5 mL of triamcinolone, 40 mg/mL, mixed with 2.5 mL of 0.5% bupivacaine). Ultrasound guidance of perineural lateral femoral cutaneous injection can significantly decrease failure rates by ensuring adequate needle localization [17].

Postinjection care may include icing of the injected area for 10 to 15 minutes and counseling of the patient to avoid pressure on the nerve.

Surgery

In the case of lateral femoral cutaneous nerve injury due to impingement, surgery may be required to remove the pressure. Surgical removal of neuroma or neurectomy proximal to the neuroma may also be helpful if a neuroma is found.

FIGURE 57.2 The nerve injection site for steroids and local anesthetic is at or near the anterior superior iliac spine.

In individuals with severe symptoms, neurolysis has been shown to result in a good outcome. This holds true even for individuals with prolonged symptoms. However, obesity has been associated with a poorer outcome when neurolysis is performed [18].

Potential Disease Complications

Potential complications include continued pain and numbness despite treatment.

Potential Treatment Complications

Complications of treatment are well recognized. Each medication has potential adverse side effects. Nonsteroidal anti-inflammatory drugs have the potential of gastric bleeding, decreased renal blood flow, and decreased platelet function. Narcotics have the potential for addiction and sedation. Carbamazepine can cause sedation and aplastic anemia. The patient taking carbamazepine should be evaluated with serial complete blood counts. Gabapentin can cause sedation. The injection of the nerve also has potential risks, which include bleeding, infection, and worsening of the pain. The potential risks of surgical intervention include bleeding, infection, and adverse reaction to the anesthetic agent.

CHAPTER 58

Piriformis Syndrome

Rathi L. Joseph, DO
Joseph T. Alleva, MD, MBA
Thomas H. Hudgins, MD

Synonyms

Hip pocket neuropathy
Wallet neuritis

ICD-9 Codes

719.45 Pain in joint, pelvic region, and thigh
729.1 Piriformis pain (musculoskeletal pain)

ICD-10 Codes

M25.551 Pain in right hip
M25.552 Pain in left hip
M25.559 Pain in unspecified hip
M79.1 Piriformis pain (musculoskeletal pain)

Definition

Piriformis syndrome describes a clinical variations of this relationship have been well documented (Fig. 58.1). Cadaver studies have described situation whereby the piriformis muscle is compressing the sciatic nerve, resulting in a sciatic neuropathy. The piriformis muscle and sciatic nerve both exit the pelvis through the greater sciatic notch. Numerous anatomic the sciatic nerve passing below the piriformis muscle, through the muscle belly, as a divided nerve above and through the muscle, and as a divided nerve through and below the muscle [1,2]. More recently, a case report of piriformis syndrome described a fifth variation of an undivided nerve passing above an undivided piriformis muscle [3]. Yeoman [4] was the first to describe the relationship of these two structures in 1928, and Robinson [5] first coined the term *piriformis syndrome* in 1947.

Although the anatomic relation of these two structures is well documented, this remains a controversial diagnosis. There is no consensus among clinicians on the validity of this entity and therefore no documentation of the incidence [6].

Some authors suggest that piriformis syndrome is responsible for up to 36% of low back pain and “sciatica” cases, whereas others found the piriformis to be culpable in less than 1% of sciatica cases [7,8]. Nevertheless, Goldner [9] estimated an incidence of less than 1% in an orthopedic practice. Prevalence is difficult to identify because the diagnosis is one of exclusion and based on clinical findings [10].

Sciatic neuropathy related to piriformis syndrome may be a result of intrinsic injury to the piriformis muscle (primary syndrome) or a compression at the pelvic outlet (secondary syndrome) [11]. Secondary causes of piriformis syndrome can include superior and inferior gluteal artery aneurysm, benign pelvic tumor, endometriosis, and myositis ossificans. Often, a history of minor trauma may be described, such as falling onto the buttock [12].

Symptoms

The patient with piriformis syndrome will complain of buttock pain with or without radiation into the leg. Sitting on hard surfaces will exacerbate the symptoms of pain and occasional numbness and paresthesias without weakness. This may be seen in chronic as well as in acute situations. Activities that produce a motion of hip adduction and internal rotation, such as cross-country skiing and the overhead serve in tennis, may also exacerbate the symptoms [13,14]. Because of the relationship of the piriformis muscle with the lateral pelvic wall, patients may also experience pain with bowel movements, and women may complain of dyspareunia [15].

Physical Examination

The physical examination will reveal normal neurologic findings with symmetric strength and reflexes. Tenderness to palpation is experienced from the sacrum to the greater trochanter, representing the area of the piriformis muscle [16]. A palpable taut band is tender with both rectal and pelvic examination because the piriformis muscle sits in the deep pelvic floor [14]. Passive hip abduction and internal rotation may compress the sciatic nerve, reproducing pain (a Freiberg sign). Contraction of the piriformis with resistance to active hip external rotation and abduction may also reproduce pain or asymmetric weakness (a Pace sign) [17]. A positive result of the straight-leg test may also be appreciated [18]. Rectal examination may be performed to palpate a taut band. See Table 58.1.

FIGURE 58.1 Three variations in the course of the sciatic nerve as related to the piriformis muscle. The sciatic nerve is shown above (3), through (2), and below (1) the piriformis muscle.

Table 58.1 Examination

Examination	Findings
Pace sign	Pain with resisted active hip external rotation and abduction with knee and hip flexed
Freiberg sign	Pain with passive hip abduction and internal rotation
Lasègue sign or straight-leg raise	Pain at greater sciatic notch with knee extension while hip is flexed to 90 degrees
Piriformis sign	Pain with tonic external rotation at the hip
FAIR testing	Pain with flexion, adduction, and internal rotation in lateral recumbent position with affected side up

Functional Limitations

The patient with piriformis syndrome will experience pain with prolonged sitting and with activities that produce hip internal rotation and adduction. This may include cross-country skiing and one-legged motions, such as the overhead serve in tennis and the kicking motion in soccer. Sitting on hard surfaces such as benches, church pews, or wallets kept in a back pocket (“wallet neuritis”) may exacerbate symptoms. Driving or sitting as a passenger in a car or other form of transportation may limit someone’s ability to get to work or to travel.

Diagnostic Testing

Piriformis syndrome is a clinical diagnosis. Magnetic resonance imaging and computed tomography are primarily reserved to rule out other disorders associated with sciatic neuropathy. A few case reports have demonstrated hypertrophy of the piriformis muscle on both computed tomography and magnetic resonance imaging [19]. Electrodiagnostic testing may reveal a prolonged H reflex in symptomatic cases [20]. This was validated by demonstration of a prolongation of the H reflex with hip flexion, adduction, and internal rotation (the FAIR test)

in symptomatic cases. Patients diagnosed with piriformis syndrome by this FAIR test demonstrated successful treatment outcomes with physical therapy and injections in 70% of the cases [21]. Electrodiagnosis is also helpful in excluding piriformis syndrome during an evaluation for lumbosacral radiculopathy. Direct magnetic resonance imaging can be useful to diagnose secondary causes of piriformis syndrome, although no radiographic criteria have been established [22].

Differential Diagnosis

Lumbar facet syndrome
L5-S1 radiculopathy [17]

Treatment

Initial

Nonsteroidal anti-inflammatory drugs and analgesic medications are prescribed to reduce local prostaglandin-mediated inflammation, pain, and spasm [14]. Judicious use of modalities, such as heat therapy, may be beneficial to increase collagen distensibility and compliance with a physical therapy program. Avoidance of exacerbating activities and use of soft cushions for prolonged sitting are also advocated initially.

Rehabilitation

The use of heat therapy, such as ultrasound, is followed by a gentle stretch of the piriformis muscle. The piriformis is stretched with hip internal rotation above 90 degrees of hip flexion and with external rotation below 90 degrees of hip flexion [21]. Strengthening of the hip abductors, in particular the gluteus medius, should be emphasized. This is performed with Thera-Band around the ankles and walking sideways. The gluteus medius may also be isolated with lunges in a transverse and coronal plane. Correction of biomechanical imbalances that may predispose the individual to piriformis syndrome should also be initiated; these include increased pronation, hip abductor weakness, lower lumbar spine dysfunction, sacroiliac joint hypomobility, and hamstring tightness [13,14]. These imbalances may lead to a gait with hip in external rotation, shortened stride length, and functional leg length discrepancy.

Procedures

Recalcitrant cases may require a perisciatic injection of corticosteroid [18]. An approach of 1 cm caudal and 2 cm lateral to the lower border of the sacroiliac joint, as seen in Figures 58.2 and 58.3, correlated to successful distribution of the injectate near the sciatic nerve area confirmed by fluoroscopic guidance and nerve stimulator [23]. A cadaveric study comparing the accuracy of fluoroscopic guidance to ultrasound guidance for piriformis injection showed ultrasound guidance to be more accurate in contrast-controlled injection. This study showed 30% accuracy in fluoroscopically guided injections versus 95%

FIGURE 58.2 With the patient in a prone, or side-lying position (shown above), the sacroiliac joint is identified with fluoroscopy (X) and the needle is inserted 1 cm caudal and 2 cm lateral to the lower border of the sacroiliac joint.

FIGURE 58.3 The needle is inserted at approximately the level of the greater trochanter (identified here with the gloved finger). A nerve stimulator is used to ensure proper placement near the sciatic nerve before introduction of the steroid solution.

accuracy in ultrasound-guided injections into the piriformis muscle [24]. Caudal epidural steroid injection to bathe the lower sacral nerve roots in corticosteroid has been described with mixed results. Injection of botulinum toxin type A (150 units) into the piriformis muscle under computed tomography guidance relieved pain and improved quality of life in a group of 20 patients with

refractory symptoms. This pain relief was significant 12 weeks after injection, much longer than a corticosteroid injection is thought to last. No head-to-head studies comparing corticosteroids to botulinum toxin have been performed [25].

Surgery

Rarely, surgical release of the piriformis muscle is performed to relieve the compression [16]. Piriformis syndrome carries a favorable prognosis; most patients will respond to a non-operative approach [13].

Potential Disease Complications

This is a clinical diagnosis that is often overlooked. The primary complication is chronic sciatica.

Potential Treatment Complications

Bleeding and gastrointestinal and renal side effects of non-steroidal anti-inflammatory drugs are well documented. Complications of local corticosteroid injections include infection, hematoma or bleeding, and soft tissue atrophy at the site. Surgical techniques must be careful to avoid inadvertent injury to the nerves in the buttock. The functional loss of sectioning of the piriformis muscle is inconsequential as the other hip abductors may compensate for this movement [16,23].

S39.011 Iliioinguinal strain (abdominal muscle)
S39.011 Inguinal muscle strain (abdominal muscle)
M85.38 Osteitis, other sites

Definition

Although there is no universally accepted definition of this condition, pubalgia is pain in the groin area that is due

to musculoskeletal causes. Despite the prevalence of the condition, the literature is filled with varying causes, anatomy involved, and terminology. Pubalgia usually refers to pain in the groin or lower abdominal area, typically in athletes who engage in activities involving repetitive sprinting, kicking, or twisting movements. Most of the published studies include athletes involved in soccer, rugby, ice hockey, running, or football. It is typically a multifactorial condition initially thought to be due to weakness of the posterior wall of the inguinal canal (Fig. 59.1). These patients have no obvious hernias or symptoms, such as numbness, clicking, a lump, or dysuria, to suggest other causes. However, medical causes need to be considered and recognized before it is concluded that the pain is due to a musculoskeletal cause [1,2]. The majority of the conditions resulting in chronic groin pain in athletes are musculoskeletal in origin [3,4]. There is ample evidence that this condition is much more common in amateur and professional athletes than in the general population [5–7].

Symptoms

The symptoms are often vague and diffuse and in the area of the lower abdomen, groin, or medial thigh. The pain is often insidious in onset and a chronic aching type [8]. Most athletes cannot remember how or when the pain started. The symptoms are worse during and after strenuous activity and exacerbated by an increase in abdominal pressure, such as coughing or sneezing. The pain may limit the ability to stand or to sit. In men, the pain can radiate into the testicle on the involved side and to the surrounding areas of the abdomen and lower back. Women may complain of a dull ache in the groin aggravated by physical exertion or intermittent neurologic pain in the distribution of the ilioinguinal nerve [9].

Physical Examination

The findings on examination can be tenderness in the area of the pubic symphysis [10,11] and pain on contraction of the hip flexors, hip adductors, or abdominal muscles [12]. Pain and tenderness at the external inguinal ring without a frank lump may be associated with pubalgia, but the presence of a lump would indicate an inguinal hernia [13]. Tenderness and dilation of the external inguinal ring can be found in up to 94% of patients with an athletic hernia [14]. Reduced range of motion of the short adductors of the hip may indicate injury to these muscles. Decreased internal hip range of motion can be due to osteitis pubis, whereas generalized

FIGURE 59.1 The anatomic layers of the groin showing the various muscles and other structures. The rectus abdominis is seen medially. (From Drake R. *Gray's Atlas of Anatomy*. New York, Churchill Livingstone, 2008.)

reduction in hip range of motion is suggestive of hip joint disease. The muscles originating from the pubic area should be palpated to assess for possible strain (adductors, sartorius, rectus femoris, and rectus abdominis). A general examination of the region should be carried out to assess for other potential causes of the symptoms. This should include examination of the testis in men and the rectum in both sexes. A gynecologic examination may be indicated in a female patient. A multidisciplinary approach to the evaluation should be considered in these patients, given the spectrum of potential diagnoses and various areas involved (abdomen, genitourinary system, musculoskeletal system) [15,16].

Functional Limitations

Pubalgia can limit activities that require repetitive hip flexion or abduction on the side of the injury. Because the pain is usually brought on by activity, it can limit athletic activities such as kicking, sprinting, or twisting.

Diagnostic Studies

Plain radiography of the pelvis can be helpful in assessing for degenerative changes involving the hips, sacroiliac joints, and lower spine. In addition, it can be helpful in assessing for other bone disease, such as stress fractures or tumors. Osteitis pubis typically produces symmetric bone resorption and sclerosis and may show widening of the symphysis [17]. Magnetic resonance imaging can be helpful in assessing the soft tissues of the pelvis and proximal thigh. It can also detect bone marrow edema about the pubic symphysis and tendon injuries [18]. Magnetic resonance imaging can help with identifying hip joint disease, such as labral tears, which too can be manifested with activity-related groin pain of insidious onset in young to middle-aged patients [18]. Selective injections can have diagnostic value in differentiating the source of pain, for example, the symphysis pubis or hip joint [19]. These are usually performed with guidance by fluoroscopy or ultrasonography. Herniography can be a sensitive way to diagnose hernias [20]. Ultrasound examination is becoming an inexpensive and noninvasive way of assessing for hernias in the groin area and tendinopathy [21].

Differential Diagnosis

- Adductor tendinopathy
- Osteitis pubis
- Sports (occult, incipient) hernias
- Conjoint tendon lesions
- Rectus abdominis tendinopathy
- Inguinal canal disease

Treatment

Initial

The patient usually presents with chronic symptoms. However, when the patient does present with an acute groin injury or groin pain, the treatment should include rest, use of nonsteroidal anti-inflammatory drugs (NSAIDs),

analgesic medications, and ice. The patient may benefit from a muscle relaxant if there are muscle spasms.

Rehabilitation

There are limited studies in the literature on the treatment of pubalgia or adductor muscle strain and no specific protocols for therapy after surgery. Clinical experience dictates that the acute treatment consist of interventions to prevent further injury and inflammation. After the acute phase, the goals are to restore range of motion of the hip and to prevent muscle atrophy and deconditioning. The muscles that tend to be weak are the ipsilateral adductors, lower abdominals, ipsilateral gluteus medius and minimus, and contralateral tensor fascia lata. The patient may require stretching of surrounding muscles and need to learn techniques to transfer with less pain. The postoperative patient can have similar deficits and may benefit from the same therapies once wound healing is stable. Friction massage of the adductors may be needed. The stretching of the adductors should start in non-weight-bearing positions and then progress to weight bearing. Finally, functional training is a crucial component of the rehabilitation program [22].

Procedures

Patients with osteitis pubis can receive relief with fluoroscopically or sonographically guided corticosteroid injections [19]. Ultrasonography is gaining in popularity to aid in the diagnosis and treatment with corticosteroid injections around the nerves (ilioinguinal, iliohypogastric, and genitofemoral) and muscle origins (adductors, rectus femoris, sartorius, and rectus abdominis) in the inguinal region.

Surgery

Many patients continue to have symptoms despite conservative treatment; therefore surgery is often an option to eliminate the pain and return them to prior activities, including sports participation. However, most of the studies are case series without comparison to nonsurgical treatment. The surgical options fall into two categories: open versus laparoscopic. However, they are not compared in any of the studies. Only one prospective, randomized study is found that involved 66 soccer players with failed conservative treatment of groin pain. The patients were randomized into four groups: open surgical repair and neurotomy, individual training, physical therapy and NSAIDs, and controls [22]. Only the surgical group was found to have a statistically significant improvement in symptoms and ability to return to sport. Other surgeries include open repair of the posterior wall deficiencies [8,23]. More recently, laparoscopic procedures have become more popular. They tout quicker recovery and good responses [14,24–26].

Potential Disease Complications

In any condition that results in chronic pain, there is the risk of secondary complications of disuse atrophy, stiffening, and reduction in the range of motion of the affected

joints and continued impact on the patient's function and quality of life.

Potential Treatment Complications

Analgesics and NSAIDs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Aggressive stretching of the adductor muscles should be avoided in the acute phase as this may cause further pain and possible strain. Herniography is an invasive diagnostic study and there can be a risk for self-resolving bowel punctures.

encounter, S—sequela)

Definition

Muscle contusions and strains account for 90% of contact sport-related injuries [1,2]. Quadriceps muscle contusions result from blunt trauma to the anterior thigh and are encountered most commonly in contact sports such as football, soccer, basketball, and wrestling. Injury is caused by a direct hit from a helmet, shoulder pad, elbow, or knee or being struck by a puck while playing hockey [3]. The acute trauma damages muscle tissue, causing hemorrhage and subsequent inflammation. A contracted muscle will absorb more force and this will result in a less severe injury [4]. At 12 to 24 hours after the injury,

quadriceps contusions are graded mild, moderate, or severe. A mild contusion has more than 90 degrees of knee flexion with normal gait; moderate, between 45 and 90 degrees of knee flexion with antalgic gait; and severe, less than 45 degrees of knee flexion with severely antalgic gait [4,5].

Symptoms

Quadriceps contusions may not be immediately evident after the contact injury. Pain, swelling, and decreased range of motion of the knee, particularly flexion, are seen within 24 hours. Symptoms may worsen with active muscle contraction and with passive stretch. Loss of knee range of motion can be the result of muscle and articular edema as well as of physiologic inhibition of the quadriceps muscle group and “splinting” due to pain. After injury, the quadriceps muscle group often becomes stiff, and the patient may have difficulty bearing weight on the affected extremity, resulting in an antalgic gait. Hemorrhage and resultant hematoma are described as either intermuscular (between the muscles) or intramuscular (within a muscle).

Physical Examination

Visual inspection of quadriceps contusion shows a variable amount of swelling and discoloration over the anterior thigh due to hematoma formation and intramuscular bleeding. Pain of varying intensity is present on palpation of the quadriceps muscle group. A firm palpable mass may be noted in the anterior thigh and is usually due to hematoma formation; if the hematoma formation is large, a knee effusion may also be present. Bone incongruity and tenderness may indicate fracture of the femur, patella, or tibial plateau. Check for the presence of distal pulses and capillary refill and assess range of motion of adjacent joints to be sure that the injury is localized to the anterior thigh.

Evaluation of range of motion reveals decreased knee flexion, especially past 90 degrees; knee extension will be less painful than flexion [6]. Extension lag or complete lack of extension is noted in partial or complete quadriceps rupture. With quadriceps tendon rupture, a palpable defect may be present. However, quadriceps rupture is a relatively rare injury more common in patients older than 50 years, and it is typically associated with underlying metabolic or inflammatory disease [7]. Muscle stretch reflexes of the patellar tendon may be inhibited, and serial measurements

of thigh circumferences should be made during the initial 24- to 72-hour postinjury period to assess for possible compartment syndrome. Paresthesias, loss of pulses, distal pallor, intense pain, and decreased temperature should alert the clinician to consider this diagnosis (see Chapter 67). Sensory testing should include the femoral and saphenous nerve distribution of the distal leg.

An intermuscular hematoma with septal or fascial sheath hemorrhage may be more likely to disperse and to result in distal ecchymosis. If the contusion is in the distal third of the quadriceps, discoloration and swelling will often track into the knee region because of gravity. An intramuscular hematoma may resolve more slowly and may be associated with myositis ossificans and scar contracture.

Functional Limitations

Initially, gait will be antalgic and weight bearing difficult on the involved extremity. Rehabilitation typically occurs in three phases. In the first phase (first 24 hours), pain usually limits activity, and the patient may require crutches [8]. During a period of days to weeks, climbing stairs, running, and “kicking” activities will be limited secondary to knee stiffness and pain associated with terminal knee flexion and extension. Most patients recover uneventfully.

Diagnostic Studies

Plain radiographs are initially obtained in moderate to severe quadriceps contusions to rule out a coexisting fracture. Magnetic resonance imaging is the diagnostic imaging study of choice and allows visualization of the involved quadriceps muscles. Resolution of the injury, as detected by magnetic resonance imaging, lags behind functional recovery [9]. Ultrasonography may be helpful if tendon injury is suspected [10]. Nuclear bone scan may be ordered in the days to weeks after injury to assess for the development of myositis ossificans traumatica, heterotopic bone formation that may develop in up to 20% of injuries. Bone scans are more sensitive than plain films for detection of heterotopic bone formation and can be useful in monitoring its resolution. Suspicion of compartment syndrome warrants consideration of intracompartmental pressure monitoring, although conservative management in cases without concomitant fracture has been reported [9,11]. Compartment syndrome may be more likely in a patient with associated fracture or suspected large-vessel injury. For severe contusions or in a patient who appears ill, laboratory work is indicated, including creatine kinase activity, hematocrit determination, and possibly coagulation studies [12].

Differential Diagnosis

- Quadriceps tear or strain
- Quadriceps tendon rupture
- Soft tissue tumors
- Compartment syndrome
- Fracture of femur, patella, or tibial plateau
- Referred pain from hip or knee
- Metabolic abnormalities leading to tendon injuries (hypocalcemia, steroid use)
- Morel-Lavallée lesion of the knee

Treatment

Initial

Immediately, the patient should cease activity. The knee is gently elevated and flexed to 120 degrees, and ice is applied to the anterior thigh (for 20 minutes at a time every 2 or 3 hours). A brace or elastic bandage should be placed around the injured leg and thigh to maintain 120 degrees of knee flexion as soon as possible after the injury and gentle compression applied to reduce hematoma formation for the initial 24-hour postinjury period [13]. After the initial 24 hours, the brace or bandage should be removed and active, pain-free range of motion of the knee should be initiated with static quadriceps strengthening and stretching [4]. If the injury is mild, icing is repeated for 2 or 3 days; the patient should ambulate with crutches, either non-weight bearing or partial weight bearing. In between icing, a thigh pad is applied. Temporary bed rest may be appropriate if the injury is severe. However, rehabilitation should be aggressive to the limit of pain tolerance. Avoid massage for the first 1 to 2 weeks after injury to lessen the chance of additional hemorrhage. Whirlpool, heat, and ultrasound modalities are avoided for the same reason until the edema stabilizes. If edema persists or becomes severe or warning signs of compartment syndrome develop, surgical referral is made to evaluate the possibility of compartment syndrome or ongoing hemorrhage. Needle aspiration of a formed hematoma may be indicated to relieve pressure and pain [14].

Determination of the appropriate time to progress the amount of activity performed and readiness for return to activity is important for recovery from injury. Animal models of muscle contusion suggest that continued use of the extremity promotes circulation and venous drainage, minimizing postinjury swelling. Because of the risk of hematoma formation, nonsteroidal anti-inflammatory drugs (NSAIDs) are avoided in the first 24 hours after injury. The role of NSAIDs in the treatment of muscle injuries is unclear because inflammatory cells are an important part of clearing away necrotic muscle followed by the regeneration and scar formation phase, leading to the question of whether NSAIDs help or delay the healing process [15]. The inflammatory response may be a necessary phase in soft tissue healing. Clinically, NSAIDs are used, but alternative analgesics like acetaminophen may be considered. However, in the animal model of quadriceps contusion, continued use of the contused muscle was more predictive of recovery than whether the animal received acetaminophen or NSAIDs [15]. Steroids should be avoided [1,4]. Medication use should facilitate continued rehabilitation and tolerance of activity progression.

Rehabilitation

Rehabilitation consists of three phases. The goals of the first phase are to limit bleeding, to immobilize the knee in full flexion, to elevate the leg for 24 hours, and to prescribe relative rest. Excessive activity or alcohol ingestion, which could aggravate the injury, is avoided. Phase two involves restoration of motion, the use of therapeutic modalities, and return to weight bearing. Crutches and partial weight bearing are used during this phase and until the patient has

at least 90 degrees of knee flexion, good quadriceps control, and limited limp. After 48 hours from the injury and for the next 2 to 5 days, test range of motion with the patient in the prone position. Perform knee flexion exercises in the “pain-free range” with associated hip flexion. This can be followed with active-assisted range of motion exercises. It is important to avoid forced stretching because this may aggravate the injury and slow healing. Static quadriceps exercises can be instituted. Animal models of muscle contusion demonstrate that early mobilization increases tensile strength of muscle compared with immobilization [16]. Proprioceptive neuromuscular facilitation exercises using reciprocal inhibition of the quadriceps and hamstrings can be done as well [17]. Modalities may include pulsed ultrasound or high-velocity galvanic stimulation, with continuous pulses of 80 to 120 per second, at the patient’s level of sensory perception for 20- to 25-minute periods. Interferential electrical stimulation may assist in further edema resolution, but both ultrasound and electrical stimulation should be used once edema has stabilized. Cautious use of ultrasound can help increase blood resorption [17]. Cold compression may be useful to decrease pain and swelling.

Phase three starts when the patient has 120 degrees of pain-free range of motion and excellent quadriceps control. Noncontact sports and other vigorous physical activities involving the lower limbs may be resumed at this point, along with active knee range of motion, progressive resistive exercises, and cycling. Pain-free knee range of motion within 10 degrees of the unaffected extremity should be the goal before return to activity is considered. Jumping, sprinting, and cutting activities should be incorporated into the rehabilitation program, at which point functional testing to assess safe return to activity can be done. In the case of athletes, a protective pad larger than the original contusion should be worn during play for 3 to 6 months after injury. Most quadriceps contusions resolve within a few weeks, and complications are rare. If the patient does not have painless, full range of motion 3 to 4 weeks after injury, radiographic imaging should be performed to detect whether myositis ossificans is present. Time to return to activity is variable and depends on severity of injury; with severe contusions, full recovery is expected within 5 to 8 weeks.

Procedures

On occasion, needle aspiration of a formed hematoma is performed to alleviate pressure and pain. This can be done at initial diagnosis or if symptoms are not responding to the measures outlined earlier.

Surgery

Surgery is rarely indicated with these injuries, except in association with a concomitant compartment syndrome or fracture. Untreated compartment syndrome may lead to muscle necrosis, fibrosis, scarring, and contractures. However, even in severe quadriceps muscle contusion, there is some indication that treatment should be conservative with pain management and maintenance of knee range of motion [9].

Potential Disease Complications

If the quadriceps region becomes extremely warm with marked increased edema and the patient complains of paresthesias with abnormal findings on neurovascular examination and significant quadriceps weakness, consideration must be given to the development of a potential compartment syndrome. A case of osteomyelitis has been reported in an otherwise healthy athlete who sustained a quadriceps contusion [18].

Myositis ossificans traumatica usually stabilizes and is resorbed spontaneously by 6 months after injury with conservative care [19]. Plain films may show ectopic bone formation 2 to 4 weeks after injury; the most common location is in the midshaft of the femur. Serial bone scans can be performed to monitor resolution of ectopic bone in a symptomatic athlete. Surgical removal of ectopic bone is rarely indicated and should not be performed for at least 12 months after injury to allow adequate maturation; this is to prevent enlargement of ectopic bone and recurrence. NSAIDs are the treatment of choice for prevention and initial treatment of myositis ossificans based on studies performed in hip replacements and related heterotopic ossification [4].

Potential Treatment Complications

Analgesics and NSAIDs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Avoid vigorous soft tissue massage and passive stretch in the acute postinjury period to prevent further bleeding and hematoma formation (this occurs frequently in a field setting after hamstring injury).

Add seventh character for categories S72, S73, and T84 for episode of care

Definition

Total hip arthroplasty (THA), commonly called hip replacement surgery, involves the reconstruction of a diseased, damaged, or ankylosed hip joint. The most common causes of adult hip disease are osteoarthritis, inflammatory arthritides, avascular necrosis, post-traumatic degenerative joint disease, congenital hip disease, oncologic bone disease, and infection involving the hip joint. The surgical treatment of hip arthritides has evolved from the first excisional arthroplasty by Anthony White in

1821 into the modern THA [1]. The modern era of hip joint replacement began in the late 1960s when Sir John Charnley combined a stainless steel femoral component with a polyethylene socket fixed to the adjacent acetabulum with polymethyl methacrylate (cement). Since that time, arthroplasty of the hip joint has become an accepted and standard treatment of common adult hip joint disease. Modern hip arthroplasty surgery has resulted in the restoration of pain-free motion and improved quality of life for millions [2]. Total joint arthroplasty, including hip and knee, has become the most common elective surgical procedure performed in the United States, with more than one million performed in 2009 [3]. The Centers for Disease Control and Prevention reported that 327,000 total hip replacements were performed in the United States in 2009 [3].

Hip joint arthroplasty can be divided into either THA, which provides a prosthetic replacement of the proximal femur and acetabulum, or hemiarthroplasty, which replaces the proximal femur while leaving the native acetabulum intact. Hip hemiarthroplasty is reserved for patients with a healthy articular surface in the acetabulum and is most commonly seen after proximal femur fractures. The focus of this chapter is on THA, which is the preferred surgical option for patients with degenerative changes affecting both the femur and acetabulum. Further categorization for hip arthroplasty can be made by prosthetic hardware components, surgical approach, or fixation method of the prosthesis (cement versus biologic or “press-fit” integration). Surgical decision-making for hardware type, approach, and prosthetic fixation is beyond the scope of this chapter, but it is important to note that there are no published consensus guidelines on best prostheses, approach, or fixation method among surgeons performing total hip arthroplasties.

Symptoms

The primary symptom of hip disease is groin pain, but patients may also have associated back and knee pain. Patients may describe a decline in mobility, self-care, and activities of daily living. They may present with an abnormal gait or may describe difficulty in walking long distances and need for an assistive device. Donning their shoes or socks and taking them off and getting in and out of the seated position may be difficult daily activities. Inability to participate in recreational activities or light sports may be a presenting complaint.

Physical Examination

Patients with hip disease are likely to have physical examination findings that will require continued attention postoperatively (Table 61.1). The examiner should examine both hips, knees, and back for range of motion. Decreased range of motion of the affected hip will be found and may be the first physical examination finding in cases of mild disease. Also, a thorough neurovascular examination of all extremities should be performed. One of the most commonly observed examination findings is an antalgic (painful) gait pattern representing a combination of pain that inhibits

Table 61.1 Goals of Rehabilitation after Total Hip Arthroplasty

Successful postoperative pain management
Maintain medical stability
Achieve successful surgical incision healing
Guard against dislocation of the implant
Prevent bed rest hazards (e.g., thrombophlebitis, pulmonary embolism, decubiti, pneumonia)
Obtain pain-free range of motion within precaution limits
Strengthen hip and knee musculature
Gain functional strength
Teach transfers and ambulation with assistive devices
Successful progression to prior living situation

Modified from Cameron H, Brotzman SB, Boolos M. Rehabilitation after total joint arthroplasty. In Brotzman SB, ed. *Clinical Orthopaedic Rehabilitation*. St. Louis, Mosby, 1996.

FIGURE 61.1 Trendelenburg sign. (From Goldstein B, Chavez F. *Applied anatomy of the lower extremities*. *Phys Med Rehabil State Art Rev* 1996;10:601-630.)

motion, structural loss of joint motion, avoidance behavior, and weakness. Hip pain or weakness of the hip abductors can result in contralateral pelvic tilt or drop (Trendelenburg sign) with ipsilateral weight bearing (Fig. 61.1). Muscle weakness is typically not true neurologic weakness but rather represents a disuse weakness associated with pain and avoidance. A hip flexion contracture may be observed with the Thomas test (Fig. 61.2), and accentuated lumbar lordosis may be seen in those with a hip flexion contracture, which may result in secondary mechanical low back pain due to alteration of normal spine mechanics. A limb length discrepancy may be observed, with the affected hip being the shorter limb.

FIGURE 61.2 Thomas test to assess a hip flexion contracture. The patient lies supine while a hip is flexed, bringing the knee to the chest and flattening the lumbar spine. The patient holds the flexed knee and hip against the chest. If there is a flexion contracture of the hip, the patient's other leg will rise off the table.

Functional Limitations

Functional limitations from severe hip disease include difficulty in walking and with all mobility, even rising from a seated position, because of pain and weakness. This may affect a patient's ability to dress, to bathe, to perform household chores, to participate in recreational activities, and to work outside the home. The goal of THA is to improve pain and consequently to improve function with activities of daily living.

Diagnostic Studies

Plain radiography remains the primary imaging tool for evaluation of hip disease and for postoperative assessment of THA. On radiographic examination, significant loss of joint cartilage as demonstrated by joint space narrowing, joint incongruity, osteophyte formation, subchondral cysts, and sclerosis are seen in individuals being considered for THA (Fig. 61.3). Many postoperative complications after THA can be evaluated by plain radiography. In patients thought to have a dislocation after THA, radiographs should be obtained urgently because a true dislocation must be relocated expediently (Fig. 61.4). Plain radiographs are also obtained in patients thought to have prosthetic loosening or periprosthetic fracture (Fig. 61.5). If plain radiographs do not show pathologic changes in a patient with enigmatic hip pain after THA, magnetic resonance imaging can be done with minimal artifact and can demonstrate disease in the periprosthetic soft tissues, including synovitis, periprosthetic inflammation, osteolysis, and iliopsoas tendinitis [4]. A computed tomography scan or bone scan may be part of the evaluation for osteolysis or loosening and infection.

Differential Diagnosis

- Infection
- Loosening of acetabular component
- Stress fracture
- Iliopsoas tendinitis with impingement
- Occult fractures
- Pelvic osteolysis
- Synovitis from metal or polyethylene debris
- Vascular disease
- Inguinal hernia
- Metastatic cancer
- Dissecting retroperitoneal disease
- Neurologic disease (including radiculopathy or spinal cord lesions)

Treatment

Treatment protocols after THA can be broadly divided into an initial (acute postoperative) phase and a rehabilitation phase. All patients will have weight-bearing and activity restrictions for approximately 6 weeks postoperatively. These restrictions are not universally accepted, are influenced by surgical technique (cemented versus uncemented fixation of the prosthesis), and can vary by surgeon preference. Ultimately, postoperative restrictions should be clarified by communication with the surgeon.

Initial

The initial phase (acute postoperative) usually includes up to 4 days after surgery and is performed on an inpatient

FIGURE 61.3 Anteroposterior pelvis radiograph showing moderate to severe degenerative changes of the hips. Notice the sclerotic changes at the acetabular and femoral heads. Note the loss of joint space, especially inferiorly, and osteophytes.

FIGURE 61.4 Total hip replacement—dislocation. The femur has dislocated superiorly and laterally relative to the acetabulum. This dislocation is due to abnormal (vertical) position of the acetabular cup that occurred from loosening (see widened cement-bone interface). (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

basis. Therapy typically begins on postoperative day 1 and focuses on getting the patient out of bed; education is provided on safe transfers, and static exercises are performed for gluteal muscles, quadriceps, and ankle pumps. Pain control strategies frequently begin with intravenous narcotics (patient-controlled analgesic pumps), cryotherapy, and appropriate education to reduce anxiety. Rehabilitation strategies on postoperative day 2 through the day of discharge should stress education on hip precautions, compliance with weight-bearing restrictions, early mobilization

FIGURE 61.5 Total hip replacement—loose femoral component. There is a wide area of lucency between the opaque cement (C) and the adjacent bone at the medial aspect of the proximal femur in addition to the area of lucency at the metal-bone interface surrounding the acetabular prosthesis. These were new findings indicative of loosening of both components. (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

with use of an assistive device, instruction on the use of adaptive equipment for functional independence (bathing, grooming), and continued pain control [5]. Pain control should be transitioned to oral medications and may require any combination of non-narcotic analgesics, nonsteroidal anti-inflammatory drugs, long-acting narcotics, or short-acting narcotics. Recently, intravenous acetaminophen has been shown to be a safe and effective pain medication in patients after joint replacement, which is of paramount importance considering the many side effects of narcotics in the elderly population [6]. Other interventions during the initial phase after THA include administration of perioperative prophylactic antibiotics, autologous blood transfusions for blood loss-induced anemia, and initiation of deep venous thrombosis prophylaxis. The patient may be receiving pharmacologic or mechanical deep venous thrombosis prophylaxis based on current clinical practice guidelines and individual patient factors [7]. By the third postoperative day, the patient should be able to tolerate 2 to 3 hours of therapy a day unless severe anemia or other medical problems result in further functional limitations. If the patient's condition is stable, the patient is ready for discharge from the acute care hospital by the third or fourth postoperative day.

Rehabilitation

Once the initial (acute postoperative) phase is complete, a decision needs to be made for the most appropriate environment for the rehabilitation phase. This decision is based on physical and social factors and should be made with the patient, the patient's primary caregiver, surgeon, physiatrist, therapists, nursing staff, and social worker. Goals for rehabilitation after THA should be to restore maximal range of

motion, to minimize pain, to improve muscle strength, to promote ambulation, and to facilitate functional independence (Table 61.1).

Hip precautions should be followed and are taught to patients to minimize the possibility of hip dislocation. Patients with weak periarticular tissues, revision surgeries, or previous dislocations are at the highest risk for a dislocation, which is greatest during the first postoperative week. Most surgeons use a posterolateral approach to the hip joint and dislocate the joint by hyperflexion (greater than 90 degrees), adduction, and internal rotation. After hip replacement, that combination of movements increases the risk of dislocation. Therefore, an abduction pillow or wedge can be placed between the legs to maintain a safe position. Patients are taught not to use low chairs or to reach forward by flexing at the hip. Many surgeons who perform THA by anterior and anterolateral approaches are advocates for these approaches because of a lessened risk of dislocation. There is level II evidence suggesting that the risk of hip dislocation is reduced with a direct anterior or anterolateral approach, and strict hip precautions are not necessary [8]. There is little information in the literature to guide the duration of hip precautions. Most surgeons encourage strict precautions for at least 6 weeks and some encourage these precautions indefinitely. The performing surgeon should clarify the prescription of hip precautions, including restricted movements and duration of precautions, before initiating any rehabilitation protocol.

Active-assisted range of motion and strengthening exercises are progressed as tolerated. Resisted hip exercises should be avoided in the first 4 to 6 weeks to prevent excessive torsional forces on the implant [5]. Strengthening exercises for knee extension are encouraged. Quadriceps weakness can persist for up to 1 year after THA if it is not addressed during rehabilitation [5]. Electrical stimulation can be used for patients with atrophy of the quadriceps. Range of motion including stretching exercises for the hip flexor and adductor muscles should be included to prevent gait abnormalities. Subjective leg length discrepancy (typically longer on the side of THA) is commonly corrected with improved posture and stretching of hip abductor muscles [5].

Early protected ambulation progresses toward independent mobility as tolerated on the basis of the individual's response and weight-bearing restrictions. Ambulation training after THA begins with appropriate assistive devices, such as a rolling walker. Weight-bearing restrictions in the postoperative phase are used to prevent "out of plane" or torsional forces on the implant. Patients should be taught to ascend stairs one step at a time and should lead with the contralateral limb to avoid torsional forces on the implant [5]. Determination of weight-bearing restrictions is made by surgeon preference and surgical technique; little literature exists to support consensus guidelines for weight-bearing restrictions after THA. However, there is some evidence to support early rehabilitation with unrestricted weight bearing after uncemented THA with a reciprocating gait pattern [9]. These patients should use protected weight bearing with stair climbing during the first weeks after surgery because of excessive forces through the hip [9]. Most patients should be able to ambulate community distances, initially with a walker or a cane, and then advance to ambulation without an

assistive device or return to their presurgical baseline within 4 to 12 weeks after hip arthroplasty. The rate of advancement in gait training is usually limited by the weight-bearing status established at the time of surgery.

Postoperative gait changes include decreased velocity, decreased stride length, decreased sagittal hip range of motion, reduced peak hip abduction, and increased peak hip flexion and extension moments [10]. Gait symmetry and velocity at 1 year after THA were most improved with supervised rehabilitation focusing on muscle strengthening and motor relearning [11].

The existing literature does not allow us to draw definitive conclusions on sports in general or high-risk activity after THA [12]. Most surgeons agree that patients should avoid contact or high-impact athletic activity after THA. Some patients can return to noncontact, low-impact athletic activity between 3 and 6 months after surgery; however, the true relationship between athletic activity and rate of revision surgery remains unclear [12]. Patients should be counseled of the details of possible complications, prosthesis failure, and revision surgery before resuming athletic activity [12].

Activities of daily living are assessed, and each individual's unique needs and goals drive the specific, individualized plan of care and treatments given. Upper and lower body bathing and dressing within hip and weight-bearing precautions are essential components of the rehabilitation program. Appropriate adaptive equipment including sock aids, reachers, and dressing sticks to perform lower body self-care should be provided. Bathroom transfers and kitchen activities are also incorporated into the rehabilitation program. Often, raised toilet seats or commodes and tub transfer benches are helpful and necessary to prevent excessive hip flexion and dislocation in the sitting position.

Discharge planning to the next level of care, including durable medical equipment, medical follow-up, and follow-up rehabilitation services (either in the home or in the community), must be communicated to the patient and family. Discharge to an inpatient rehabilitation facility has been influenced by the Centers for Medicare and Medicaid Services, which has determined that hospitals are eligible for payment of rehabilitation after total joint arthroplasty if (1) it is a bilateral procedure, (2) age is older than 85 years, or (3) body mass index is above 50. A typical total hip replacement clinical pathway or protocol for inpatient rehabilitation is now a 7- to 10-day program [13]. Many published sources outline the benefits as well as the elements of the total hip replacement clinical pathway; however, there is a need to update the literature, given the changes in surgical technique [14–16]. There is also a shift toward rapid discharge to home from acute care with an outpatient rehabilitation program, especially in the era of minimally invasive surgery [17]. A Cochrane review with silver level of evidence showed that early multidisciplinary rehabilitation can improve outcomes with regard to activity levels and postoperative participation [18]. There is a paucity of literature discussing the optimal intensity, frequency, cost-effectiveness, and long-term effects of early multidisciplinary rehabilitation.

Individuals who undergo THA revision surgery have a more difficult postoperative rehabilitation experience; they often show less progress in functional independence

measures, longer rehabilitation length of stay, and greater hospital charges compared with patients undergoing primary hip replacement surgery. These differences in outcomes are even more pronounced if an infected prosthesis is the cause of the revision arthroplasty [19].

Procedures

Wound care, staple or suture removal, and Steri-Strip application are typically performed after THA.

Surgery

Most surgeons will consider THA if a patient is having severe pain that is affecting the patient's quality of life, there are signs of degenerative joint disease on radiographs, and the patient has maximized conservative treatment options. However, there are no minimum standards or universally accepted criteria for patient selection. Patient selection may also be influenced by the patient's ability to cooperate with the rehabilitation program after surgery, serious comorbid medical conditions, morbid obesity, high levels of activity, high fall risk, or younger age [20]. These factors can contribute to early failure and complications. Contraindications include local or systemic infection, neuromuscular compromise, dementia, poor bone quality, and poor vascular supply.

The THA components include a femoral stem, a femoral neck, a femoral head, and an acetabular shell or cup with a polyethylene liner (Fig. 61.6). This allows resurfacing of both sides of the hip joint and permits the highest degree of "customization" for each individual. Surgical technique and decision-making are beyond the scope of this text; however, there are some considerations that will have implications for rehabilitation.

Rehabilitation of THA will be affected by fixation techniques: cemented versus uncemented. The cemented technique is used only on the femoral component. After a cement restrictor plug is placed in the distal femoral canal, polymethyl methacrylate cement is freshly made and inserted into the femoral canal by pressurized cementing technique. Insertion of the femoral stem creates an intimate fit of the prosthesis to the intramedullary canal with a small circumferential cement mantle. Cement polymerization rigidly fixates the femoral component. Frequently, the patient with a cemented prosthesis is allowed to bear weight as tolerated immediately, whereas the individual with a noncemented press-fit prosthesis often must wait for 6 to 8 weeks before fully bearing weight to allow stability by bone ingrowth. Rehabilitation will also be affected if surgical technique includes trochanteric osteotomy. If a trochanteric osteotomy is performed during the surgery, hip abduction resistance exercises are usually restricted.

The changing population of patients undergoing THA is driving the current trends in THA. The high-demand, younger patient population with hip disease has led to the use of alternative bearing surfaces (ceramic-ceramic articulations, metal-on-metal articulations, and improved polyethylene surfaces). These alternative bearing surfaces are intended to improve durability and wear for highly active patients. There is growing interest in the orthopedic literature on the safety and outcomes of these alternative surfaces; however, there is no superior articulation at this time. Less invasive

FIGURE 61.6 The components of a total hip replacement.

and minimally invasive approaches have been developed to facilitate rehabilitation and to decrease rehabilitation time. Navigation technology has been used in total knee arthroplasty but is now being considered to assist with implant positioning in hip replacement (particularly with the use of minimally invasive approaches). Bone-preserving techniques, including resurfacing techniques and short-stemmed femoral implants, have also been considered for the younger and more active patients undergoing THA. The long-term effects and outcomes of these trends have yet to be determined in the literature but are currently being studied.

Whereas all patient subgroups have demonstrated functional improvements from joint arthroplasty, younger age and male sex are associated with the increased risk of revision surgery. In one systematic review, older age and male sex are associated with increased mortality, and older age (particularly in women) is related to worse function after arthroplasty [21].

Potential Disease Complications

Common physical impairments of hip disease after THA include decreased muscle strength, limited hip range of motion, limited flexibility, and abnormalities of gait. Hip joint weakness has been shown to persist at 2 years after surgery, indicating a need for prolonged exercise. Current data suggest that THA patients continue to experience physical and functional limitations lasting at least 1 year postoperatively. Persistent groin pain after an otherwise successful surgery has

been documented in as high as 18% of total hip arthroplasties [22]. Therefore it is reasonable to have patients continue with therapeutic exercises to address these limitations well beyond the early recovery period (first 12 weeks) [23,24].

Potential Treatment Complications

Perioperative and postoperative complications after THA include infection, deep venous thrombosis, pulmonary embolism, dislocation, periprosthetic fracture, nerve injury, iliopsoas impingement, limb length inequality, anemia, bleeding, myocardial infarction, and death.

The incidence of deep venous thrombosis after total hip implantation without prophylactic anticoagulation is 45% to 57%; the incidence of proximal clot (defined as any thrombosis in the popliteal vein or more proximal) is between 23% and 36%; and the incidence of fatal pulmonary embolism is between 0.7% and 30% [25]. Clinical practice guidelines encourage surgeons to assess the thrombosis and bleeding risk for each individual patient and help guide which prophylactic treatment is indicated [6]. Postoperative limb swelling should trigger deep venous thrombosis surveillance screening with venous ultrasonography and Doppler wave signal analysis (commonly referred to as duplex scanning). If pulmonary embolism is suspected in a patient with hypoxia or shortness of breath, chest radiography, electrocardiography, and ventilation/perfusion scanning or computed tomographic pulmonary angiography are included as part of the evaluation.

Careful attention is given to treatment of anemia because patients with adequate hemoglobin levels generally tolerate activity well and progress in rehabilitation more readily than do those with low hemoglobin levels. Adequate nutrition, iron supplements, vitamins, and, if needed, erythropoietin can be used. Blood transfusions may be necessary if the hemoglobin level continues to drift downward and there is concern of hemodynamic instability or if the patient has symptoms or physical examination findings indicative of low perfusion status.

A hip dislocation is not subtle and should be suspected if the patient cannot endure weight bearing, the limb is acutely shortened and internally rotated, or the patient is intolerant of gentle hip motion because of excessive pain. A patient can usually give an exact moment or event that led to the dislocation. A dislocation often results in a significant functional setback as the patient is often more cautious and fearful of performing activities of daily living and mobility training. Reduction typically requires sedation and muscle relaxation and may require a return trip to the operating room.

Wound care of the incision line is accomplished with dry sterile dressing changes once or twice a day. Once wound drainage ceases, a dressing is no longer essential. Tape burns around the surgical incision are a common problem and can be treated with a hydrogel pad such as DuoDerm for approximately 1 week. Serous drainage without signs of erythema or induration is commonplace for 3 or 4 days postoperatively, but persistent drainage beyond 7 days should trigger clinical suspicion for wound infection. Wound problems should be communicated to the operative surgeon for collaboration on additional management including cultures, antibiotics, and more invasive intervention if necessary.

Late prosthetic hip infection by a hematogenous source can be a serious complication, often requiring extensive hospitalization, intravenous administration of antibiotics, and removal of the hip prosthesis. Eventual reimplantation is done after the infection is eradicated. Currently, there is no consensus for antibiotic prophylaxis before invasive procedures (dental work, colonoscopy). Most surgeons do recommend antibiotic prophylaxis for their patients after THA, but there is no consensus on how long after THA, if not indefinitely, they should have antibiotic prophylaxis.

Iliopsoas impingement can cause significant pain in the otherwise successful THA patient. Typically, the culprit is iatrogenic, from an oversized acetabulum component with anterior overhang, relative retroversion of the components, or protrusion of fixation screws, which results in iliopsoas tendinitis from tendon impingement.

CHAPTER 62

Greater Trochanteric Pain Syndrome

Michael Fredericson, MD

Cindy Lin, MD

Kelvin Chew, MBBCh, MSpMed

Synonyms

Trochanteric bursitis
Hip bursitis
Gluteus medius tendinopathy

ICD-9 Codes

719.45 Pain in hip joint
726.5 Trochanteric bursitis
843.8 Tear/sprain of gluteus muscle
(hip and thigh)
726.5 Tendinitis of hip region

ICD-10 Codes

M25.551 Pain in right hip
M25.552 Pain in left hip
M25.559 Pain in unspecified hip
M70.60 Trochanteric bursitis of hip,
unspecified hip
S76.001 Injury of muscle, fascia and tendon
of right hip
S76.002 Injury of muscle, fascia and tendon
of left hip
S76.009 Injury of muscle, fascia and tendon
of unspecified hip
Add seventh character to S76 for episode of
care (A—initial encounter, D—subsequent
encounter, S—sequela)
M70.61 Trochanteric bursitis of hip, right hip
M70.62 Trochanteric bursitis of hip, left hip
M76.00 Gluteal tendinitis, unspecified hip
M76.01 Gluteal tendinitis, right hip
M76.02 Gluteal tendinitis, left hip

Definition

Greater trochanteric pain syndrome (GTPS) is a common cause of lateral extra-articular hip pain. GTPS is clinically characterized by peritrochanteric pain and focal tenderness [1]. GTPS describes a continuum of disorders with causes ranging from gluteus medius and minimus tears, tendinitis, or tendinopathy to trochanteric bursitis and external coxa saltans [2]. Previously, it was thought that excessive gluteal tendon friction at the greater trochanter attachment led to subgluteus maximus bursal inflammation; hence, it was called greater trochanteric bursitis [3]. However, histopathologic and imaging studies have not identified bursal inflammation as a consistent finding, thus leading to the current clinical description of this entity as GTPS [2].

The peak incidence of GTPS is between the fourth and sixth decades of life. It occurs four times more frequently in women than in men, which may be due to gender differences in pelvic and lower limb biomechanics [4,5]. It affects up to 10% of the general population and has been reported in up to 20% of patients with low back pain [5,6]. GTPS can result from direct macrotrauma after contusions from falls or contact sports [7]. However, it is more often due to cumulative microtrauma and abnormal loading forces on the gluteus medius and minimus tendons inserting on the greater trochanter. It has been suggested that gluteal tendon degeneration and tears at the greater trochanter attachment may induce secondary reactive inflammation in the bursae [4]. Contributing factors include hip or knee osteoarthritis, lumbar spine degenerative disorders, obesity, true or functional leg length discrepancies, gait abnormalities, and iliotibial band tightness [5,6,8]. GTPS can also occur after hip surgery, such as femoral osteotomy [9], hip joint replacement, or arthroscopic surgery, and from postoperative hip abductor weakness. Less common causes to consider in the differential diagnosis include infection and inflammatory arthritis if there are systemic symptoms and signs, lateral hip swelling, redness, or heat [10–12].

The greater trochanter of the femur is the insertion site of the gluteus medius, gluteus minimus, piriformis, and obturator internus muscles, and it is also the origin of the vastus lateralis muscle [13]. Three main bursae surround the greater

trochanter, including the subgluteal maximus, medius, and minimus bursae [14]. The subgluteus maximus bursa is the largest bursa and lies lateral to the greater trochanter beneath the gluteus maximus and iliotibial tract. The subgluteus medius bursa lies deep beneath the gluteus medius tendon and posterosuperior to the lateral facet of the greater trochanter. The subgluteus minimus bursa lies beneath the gluteus minimus tendon at the anterosuperior edge of the greater trochanter. The subgluteus maximus bursa is most often involved in cases of trochanteric bursitis [3].

Symptoms

The main clinical symptom is lateral hip pain at the greater trochanteric region. The pain can radiate down the lateral aspect of the thigh as a pseudoradiculopathy that does not extend past the knee. Symptoms are exacerbated by hip movements, in particular external rotation and abduction. Pain may also be provoked by standing, walking, stair climbing, crossing the legs, running, or running on banked surfaces. Recent changes in physical activity or sports training programs may precede symptoms. Sleep may be affected with pain aggravated by lying in the lateral decubitus position directly on the affected side or from lying with the affected side up and in passive hip adduction.

Physical Examination

In GTPS, localized tenderness is found on direct palpation of the greater trochanter. Lateral hip pain may be reproduced on examination with resisted hip abduction with the patient in a side-lying position. Pain can also be elicited with active hip internal or external rotation at 45 degrees of hip flexion [15].

Evaluation for gait, hip, or spine disorders and leg length discrepancy is important as abnormal motion and joint loading in one region of the kinetic chain can contribute to the development of GTPS. The Trendelenburg sign can be seen in GTPS as a result of weakness or inhibition of the hip abductor muscles [16]. The gluteus medius and minimus play an important role in hip abduction and pelvic stabilization during gait. In GTPS, with weight bearing on the affected limb during single-leg stance, the hip abductors are unable to stabilize the pelvis, resulting in contralateral pelvic drop [17]. Activity-related pain, particularly in the anterior groin, or restricted hip range of motion may indicate intra-articular hip

disease, such as osteoarthritis, femoroacetabular impingement, or labral disorders that warrant further investigation. Lumbosacral radiculitis or radiculopathy should be ruled out with detailed history and neurologic examination; the neurologic examination findings should be normal in GTPS.

Functional Limitations

GTPS can limit activity and mobility and cause further weakness of the lateral hip rotator muscles and deconditioning. This can have an impact on basic activities of daily life, including walking, running, and stair climbing. Pain may also interrupt sleep.

Diagnostic Studies

Laboratory studies, although seldom required, should be performed if an infectious or rheumatologic process is suspected. The diagnosis of GTPS can usually be made by history and physical examination. Imaging studies are used mainly to exclude other underlying causes of lateral hip pain or when symptoms do not respond to conservative treatments.

Magnetic resonance imaging can be useful in cases in which there is clinical concern for other causes of lateral hip pain. Magnetic resonance imaging or ultrasonography can be used to detect tendinopathy, muscle tears, cortical irregularity, bursal fluid or thickening, or muscle atrophy [18,19]. The identification of bursal fluid on magnetic resonance imaging or ultrasound examination is thought to be a secondary manifestation of local disease rather than the primary process in most cases of GTPS [18].

Ultrasound examination can be helpful in visualizing the muscle insertions on the facets of the greater trochanter to localize the pathologic process. The insertion for the gluteus minimus tendon is the anterior facet; for the gluteus medius tendon, the lateral and superolateral facets; and for the subgluteal maximus and trochanteric bursa, the posterior facet (Fig. 62.1) [20]. A “bald” facet, with absence of the tendinous insertion, suggests a complete tear. Anechoic defects within the tendon suggest partial tears. Gluteal tendinosis on ultrasound examination is identified by tendon thickening, heterogeneous signal, and decreased echogenicity [18].

Hip plain films may demonstrate calcifications in the region of the bursa or in the gluteal tendon insertions related to calcific tendinosis [2,18].

FIGURE 62.1 Anatomy of greater trochanter with tendinous insertion sites and bursae. **A**, The three main bursae and their positions. **B**, Geometry of greater trochanter with different facets. **C**, Footprints of gluteus medius and minimus tendon insertions. (Modified from Domb BC, Nasser RM, Botser IB. Partial-thickness tears of the gluteus medius: rationale and technique for trans-tendinous endoscopic repair. *Arthroscopy* 2010;26:1697-1705.)

Differential Diagnosis

Osteoarthritis of the hip
Lumbosacral radiculopathy
Lumbosacral radiculitis
Leg length discrepancy
Avascular necrosis of the femoral head
Iliotibial band syndrome
Hip stress fracture
Acetabular labral disease
Tumors

Treatment

Initial

Initial treatment is to provide acute pain relief through icing, analgesic pain medications, and sports and activity modification, such as avoidance of stair climbing and other exacerbating activities. Direct pressure on the painful lateral hip should be avoided; as such, recommendations on sleep positioning can be given. Gentle stretching of the iliotibial band, tensor fascia lata, and gluteal muscles is encouraged with avoidance of end-range hip motion in the acute phase.

Rehabilitation

Physical therapy entails a combination of strengthening, stretching, and correction of identifiable underlying spine or hip disorders that precipitated GTPS. Strengthening should focus on the core and hip abductors, extensors, and external rotators with progression to eccentric loading of the gluteal muscles in cases of tendinopathy. Myofascial soft tissue release, stretching, or therapeutic ultrasound may be helpful for the tensor fascia lata–iliotibial band complex.

Focal ice massage may be useful at the outset of the injury. Extracorporeal shock wave therapy can be beneficial for pain relief during the subacute to chronic phases [21]. Addressing gait abnormalities through orthotics or assistive devices, such as walkers or canes, should also be considered. Weight loss is advised in obesity.

Procedures

For cases unresponsive to noninvasive treatments, corticosteroid injections combined with local anesthetic can be used. Whereas some studies have found corticosteroid injections to be effective in the short term in improving pain and activity, other studies report incomplete long-term relief and symptom recurrence [21–24]. The injection technique involves the patient's lying in the lateral decubitus position with the affected side up and the knees flexed comfortably. The point of maximal tenderness over the greater trochanter is identified and marked. Under sterile conditions, a syringe with a 25-gauge needle, containing triamcinolone (40mg) with 1% lidocaine (3 to 4mL), is advanced until contact is made with the greater trochanter bone; the needle is then withdrawn 3 or 4mm. Once negative aspiration has verified that the needle is not intravascular, the solution is introduced after a lack of resistance is detected.

Patients are reevaluated within a month after injection to assess therapeutic response.

Ultrasound or fluoroscopic guidance may be used to enhance precise injection placement. However, fluoroscopically guided trochanteric injections have not been found to be superior to blind injections in terms of patient outcomes and are associated with increased cost [24]. Caution must be exercised with repeated injection because it may be associated with muscle and tendon weakening or rupture [25].

Surgery

In refractory cases and if significant functional limitations are present, surgery can be considered. Depending on the underlying pathologic process, this may involve arthroscopic bursectomy [26], iliotibial band release or lengthening, or open or endoscopic gluteal tendon repair [20,27,28].

Potential Disease Complications

GTPS should be a self-limited condition. If symptoms persist, consider other underlying causes. If the underlying predisposing factors are not appropriately addressed, the syndrome may progress to chronic pain, which can lead to muscle deconditioning, hip abductor muscle weakness, functional decline, and increased risk of falls in elderly or frail patients.

Potential Treatment Complications

Complications from anti-inflammatory medications include drug hypersensitivity, gastric ulceration, and renal toxicity. Complications from corticosteroid injections include bleeding, bruising, infection, drug hypersensitivity reactions, tendon ruptures, nerve injury, fat atrophy, and skin hypopigmentation [23,25].

Knee and Leg

CHAPTER 63

Anterior Cruciate Ligament Tear

William Micheo, MD

Eduardo Amy, MD

Fernando Sepúlveda, MD

Synonyms

Anterior cruciate ligament (ACL) tear
ACL sprain
ACL-deficient knee

ICD-9 Codes

717.83 Old disruption of anterior cruciate ligament
844.2 Cruciate injury, acute

ICD -10 Codes

M23.611 Spontaneous disruption of anterior cruciate ligament of right knee
M23.612 Spontaneous disruption of anterior cruciate ligament of left knee
M23.619 Spontaneous disruption of anterior cruciate ligament of unspecified knee
S83.104 Dislocation of right knee
S83.105 Dislocation of left knee
S83.106 Dislocation of unspecified knee

Definition

The anterior cruciate ligament (ACL) is an intra-articular structure essential for the normal function of the knee. It is commonly injured during activities that involve complex movements, such as cutting and pivoting. It is estimated

that 1 in 3000 individuals sustains an ACL injury each year in the United States, corresponding to an overall injury rate of approximately 100,000 injuries annually [1]. The injury usually results from a sudden deceleration during high-velocity movements in which a forceful contraction of the quadriceps muscle is required. Other mechanisms of injury are valgus stress, hyperextension, and external rotation, as in landing from a jump, and severe internal rotation of the knee with varus or hyperextension [1]. Approximately 70% of the acute ACL injuries are sports related and affect women more than men, particularly in sports such as basketball and soccer [2]. Non-sports-related injuries might include a patient slipping on ice or falling from considerable height and landing with the knee in hyperextension and valgus. In the last two decades, there has also been an increase in the incidence and appropriate diagnosis of ACL injuries in children associated with more participation in high-demand contact and noncontact sports, increased awareness of the injury, and better imaging techniques [3]. Risk factors associated with ACL injuries can be classified as anatomic, hormonal, environmental, biomechanical, and neuromuscular. Some of the modifiable risk factors include proprioception, core strength, decreased hamstring strength (relative to quadriceps strength), conditioning, footwear, playing surface, weather conditions, training techniques, and biomechanical variations in landing from a jump or cutting. Nonmodifiable factors include gender, reduced femoral intercondylar notch size, increased slope of the tibial plateau, knee hyperextension, physiologic rotatory laxity, small ACL size, and familial predisposition [1,4-6].

The ACL may be partially or completely torn. It also may be injured in combination with other structures, most commonly tears of the medial collateral ligament and medial meniscus.

The ACL is a collagenous structure approximately 38 mm in length and 10 mm in width. The ligament arises from

a wide base in the tibia anterolateral to the anterior tibial spine. It then traverses the knee in a posterolateral direction, attaching in a broad fan-like fashion at the posterolateral corner of the intercondylar notch of the femur. According to Fu and collaborators, it is organized in two major bundles named after their insertion sites on the tibia [7]. The antero-medial bundle, which tightens in flexion and is the longer of the two, controls anterior translation of the tibia on the femur. The posterolateral bundle, which tightens in extension and internal rotation, controls rotation [8–10].

Biomechanical studies, with use of cadaver specimens, have evaluated the forces that affect the ACL [11]. These forces are highest in the last 30 degrees of extension, in hyperextension, and under other load conditions, including anterior tibial translation, internal rotation, and varus. The ACL is a static stabilizer of the knee with a primary function of resisting hyperextension and anterior tibial translation in flexion and providing rotatory control. It is also a secondary restraint to valgus and varus forces in all degrees of flexion.

Symptoms

Individuals usually present with pain, immediate swelling, and limited range of motion. They may give a history of hearing a “pop.” In an acute injury, the individual will have severe pain and difficulty with walking. In a chronic injury, a patient may have a history of recurrent episodes of knee instability associated with swelling and limited motion. Patients may describe locking or a “giving way” phenomenon. They may also give a history of a remote injury to the knee that was not rehabilitated.

Physical Examination

The physical examination has been found to be sensitive and specific in the diagnosis of ACL tears and correlates with arthroscopically documented knee injuries [1]. The clinician should observe the knee for asymmetry, palpate for areas of tenderness, measure active and passive range of motion, and document muscle atrophy. The apprehension test to rule out patellar instability, valgus and varus testing with the knee in full extension and 30 degrees of flexion to evaluate the collateral ligaments, and joint line palpation as well as the McMurray test to evaluate the meniscus are all important tests to look for injury of associated structures.

The key physical examination maneuver for evaluating the integrity of the ACL in the patient with an acute injury is the Lachman test, in which an anterior force is applied to the tibia with the knee in 30 degrees of flexion while the clinician tries to reproduce anterior migration of the tibia on the femur (Fig. 63.1). Another important test in the acute setting is the lateral pivot shift maneuver, in which the examiner attempts to reproduce anterolateral instability by internally rotating the leg, applying a valgus stress to the knee as it is flexed, and feeling for anterior migration of the tibia on the femur (Fig. 63.2). After injury, the Lachman test is most important for acute diagnosis, whereas the lateral pivot shift test has shown a better correlation to future sports participation and functional stability [1,12]. In the patient who is able to flex the knee to 90 degrees, particu-

FIGURE 63.1 Position for the Lachman test. The knee is flexed at 20 to 30 degrees. The distal femur is stabilized with one hand while the other hand pulls the proximal tibia anteriorly.

larly in chronic or recurrent injury, the anterior drawer test, in which an anterior force is applied to the tibia, should be performed (Fig. 63.3). In acute injury, this test may provide a false-negative result because the secondary stabilizers may reduce anterior tibial displacement with the knee in 90 degrees of flexion [13]. It is important to complete the examination by performing the posterior drawer test, which evaluates the posterior cruciate ligament; a torn posterior cruciate ligament with posterior tibial subluxation may give a false-positive result of the anterior drawer maneuver as the tibia is reduced. In general, findings should be normal on the neurologic examination, including muscle strength, sensation, and reflexes; however, there may be some associated weakness (particularly of the knee extensors) due to pain inhibition or disuse.

Functional Limitations

Limitations include reduced knee motion, muscle weakness, and pain that interferes with activities involving pivoting and jumping. Recurrent episodes of instability may limit participation in strenuous sports, such as basketball, soccer, tennis, and volleyball [14,15]. These episodes of the knee's giving way may result in increased ligamentous laxity, leading to limitations with activities of daily living, such as going down stairs and changing directions while walking.

Diagnostic Studies

Diagnostic studies include plain radiographs to rule out intra-articular fractures (tibial spine avulsion, Segond fracture), loose bodies, and arthritic changes. These include the standing anteroposterior view, lateral view, tunnel view, standing posteroanterior 45-degree flexion view, and Merchant view of the patella. Magnetic resonance imaging may be indicated in the acute setting to evaluate associated pathologic changes, such as bone bruises, meniscal tears, and other ligamentous injuries, and to aid in treatment planning of combined injuries. In the pediatric and adolescent athlete, magnetic resonance imaging may also give information about physeal injuries that may otherwise go unnoticed.

FIGURE 63.2 Position for the lateral pivot shift test. **A**, Note that the patient's knee is fully extended. Internally rotate the leg and apply a valgus stress. **B**, As you flex the knee between 20 and 45 degrees, the lateral tibial plateau is subluxed. **C**, As tension in the iliotibial band is lessened at 45 degrees of flexion, a pivot shift is felt as the tibia is reduced. This test identifies a rupture of the anterior cruciate ligament.

FIGURE 63.3 Position for the anterior drawer test. The hip is flexed 45 degrees, the knee is flexed 90 degrees, and the tibia is in neutral rotation. Anterior pull can be applied to the proximal tibia with both hands.

Differential Diagnosis

- Isolated ACL tear
- Combined lesions
 - Posterolateral ligamentous complex tear
 - Medial collateral ligament and medial meniscus
- Intra-articular fracture
- Patellar dislocation
- Meniscal tear

Treatment

Initial

Immediately after injury, the management of an ACL tear includes relative rest, ice, compression, elevation, and analgesic or anti-inflammatory medication. Many patients will initially benefit from use of a knee immobilizer and crutches. If the knee is very swollen and painful with limited motion

that restricts participation in treatment, arthrocentesis may be performed. It is important to establish an accurate diagnosis and the presence of associated injuries as these may necessitate prompt surgery. These include chondral or osteochondral fractures, meniscal tears, and other injured capsular structures. In general, in the absence of associated injuries, the acute management can be conservative with early protected rehabilitation.

Treatment of ACL injuries depends on a number of factors, including the patient's age, level of activity, presence of associated injuries, and importance of returning to athletic activities that involve acceleration and deceleration and cutting moves. Surgery is the only definitive treatment of complete ACL injuries, but it is generally not necessary for older individuals who do not complain of knee instability with recreational activities or work.

In general, younger patients and those with a high activity level should be considered for ACL reconstruction. Surgical referral is not necessary in the immediate postinjury period but should be facilitated as soon as it is clear that an individual desires surgery as a definite treatment measure. When associated injuries are present, especially if these cause mechanical symptoms, or in the case of the elite competitive athlete, surgical treatment should be considered as soon as the initial inflammatory phase has passed (Fig. 63.4) [16].

Rehabilitation

The rehabilitation of an ACL tear begins as soon as the injury occurs. Rehabilitation management focuses on reducing pain, restoring full motion, correcting muscle strength deficits, achieving muscle balance, and returning the patient to full activity free of symptoms [17]. The rehabilitation program consists of acute, recovery, and functional phases.

Anterior Cruciate Ligament Injury

The patient with an ACL-deficient knee may present with an acute or a recurrent injury. In the acutely injured knee, protection of secondary structures is of paramount importance, and progression of rehabilitation will depend on

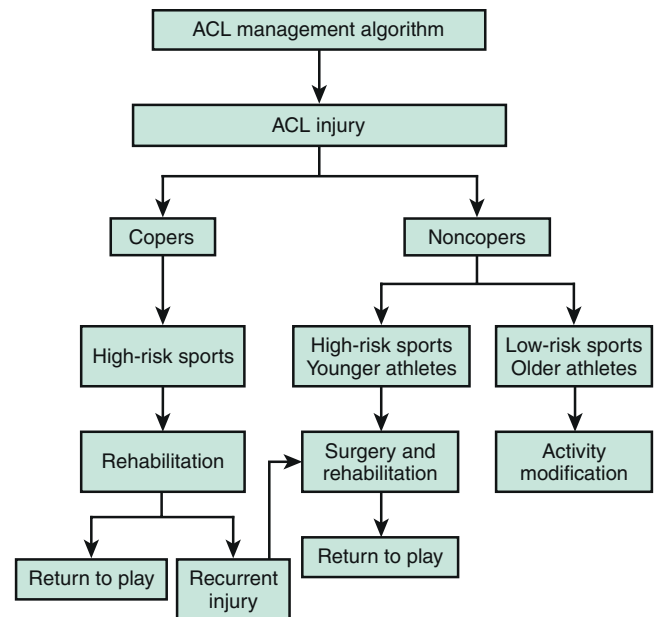

FIGURE 63.4 University of Puerto Rico Center for Sports Health anterior cruciate ligament (ACL) injury management algorithm. (From Micheo WM, Hernandez L, Seda C. Evaluation, management, and prevention of anterior cruciate ligament injury: current concepts. *PM R* 2010;2:935-944.)

the extent of damage to other knee structures. Early use of closed kinetic chain exercises, in which the distal segment of the extremity is fixed and the proximal segments are free to move, has allowed functional progression of strengthening. These exercises allow quadriceps strengthening with hamstring muscle co-contraction, which reduces the strain in the ACL and minimizes patellofemoral joint reaction forces (Table 63.1) [17,18].

The individual with a recurrently unstable knee will benefit from a trial of rehabilitation. Correction of muscle weakness and proprioceptive deficits and functional retraining in combination with activity modification could reduce

Table 63.1 Anterior Cruciate Ligament Tear Rehabilitation

	Acute Phase	Recovery Phase	Functional Phase
Therapeutic intervention	Modalities: cryotherapy, high-voltage galvanic stimulation, electrical stimulation Active-assisted flexion and extension Static quadriceps and hamstring exercise General conditioning: bicycle and pool exercises Ambulation with crutches	Modalities: superficial heat, pulsed ultrasound, electrical stimulation Range of motion, flexibility exercises Dynamic lower extremity strengthening Closed kinetic chain exercises, multiplanar lower extremity joint exercises General conditioning Gradual return to sports-specific training with functional bracing	General flexibility, strengthening training Power and endurance of lower extremities: diagonal and multiplanar motions, plyometrics Neuromuscular control, proprioceptive training Return to sports-specific participation with functional bracing
Criteria for advancement	Pain reduction Recovery of pain-free motion Adequate knee muscle control Tolerance for strengthening exercises	Full nonpainful motion Symmetric quadriceps and hamstring strength Correction of inflexibility Symptom-free progression in a sports-specific program	No clinical symptoms Normal running and jumping mechanics Normal kinetic chain integration Completed sports-specific program

episodes of instability and should be considered before surgery in the individual with low activity levels.

Acute Phase

This phase focuses on treatment of tissue injury, clinical signs, and symptoms. The goal in this stage is to allow tissue healing while reducing pain and inflammation. Reestablishment of nonpainful range of motion, prevention of muscle atrophy, and maintenance of general fitness should be addressed. This phase may last 1 to 2 weeks.

Recovery Phase

This phase focuses on obtaining normal passive and active knee motion, improving knee muscle function, achieving normal hamstrings and quadriceps muscle balance, and working on proprioception. Biomechanical and functional deficits, including inflexibilities and inability to run or jump, should begin to be addressed. This phase may last 2 to 8 weeks after the injury occurs.

Functional Phase

This phase focuses on increasing power and endurance of the lower extremities while improving neuromuscular control. Rehabilitation at this stage works on the entire kinetic chain, addressing specific functional deficits. This program should be continuous with the ultimate goal of prevention of recurrent injury and safe return to competition. The functional phase may last 8 weeks to 6 months after the injury occurs.

If the patient completes a rehabilitation program and is willing to modify the activity level, including the limitation of sports activity that involves cutting and pivoting maneuvers, the functional prognosis for daily living activities is good [11,19]. In this group of patients, functional braces may be used for sports participation that involves changes of direction. These braces may reduce symptoms of instability in individuals who use them, improve proprioception, and

appear to reduce some strain in the ACL in low-demand activities.

Postsurgical Rehabilitation

In the patient who is a candidate for ACL reconstruction, rehabilitation should start before surgery. Reduction of pain and swelling, achievement of full range of motion, voluntary muscle activation, and finally achievement of normal muscle strength should be attempted before reconstruction. After surgery, rehabilitation should begin on the first postoperative day. Early use of cryotherapy, compression, and elevation has been shown to reduce swelling postoperatively. It is important to achieve full extension and to initiate early active flexion in the first few days after surgery. Weight bearing with crutches is usually started immediately after the operation [20].

Rapid progression of the rehabilitation program has reduced complications usually associated with ACL knee surgery, which included stiffness, muscle atrophy, muscle weakness, and patellofemoral pain. In the early rehabilitation period, special precautions need to be taken to avoid excessive strain of the reconstructed ligament with terminal (0 to 30 degrees) extension-resisted quadriceps exercises. Early use of closed kinetic chain exercises, such as mini-squats, steps, and leg press, has allowed quadriceps strengthening with tolerable shear forces to the graft [17,18,20] (Table 63.2). Aquatic exercises that allow progressive weight bearing with benefit from the effects of buoyancy can be started as soon as the sutures are removed.

Individuals will vary in the rate in which they achieve full motion, normal strength, normal proprioception, and adequate sports-specific skills. Achievement of these goals should be accomplished before the individual is allowed to return to sports activity. With accelerated rehabilitation programs, patients usually return to activity in 6 to 8 months after surgery. These accelerated rehabilitation programs do not lead to an increase in anterior knee

Table 63.2 Postsurgical Anterior Cruciate Ligament Tear Rehabilitation

	Acute Phase	Recovery Phase	Functional Phase
Therapeutic intervention	Modalities: cryotherapy, electrical stimulation Active-assisted flexion, passive extension Static quadriceps (90 to 45 degrees), dynamic hamstrings exercises, straight-leg raise exercises General conditioning: upper extremity ergometer Ambulation with crutches	Modalities: superficial heat, pulsed ultrasound, electrical stimulation Active flexion and extension exercises Dynamic quadriceps (90 to 30 degrees), hamstring strengthening Closed kinetic chain exercises, multiplanar lower extremity joint exercises General conditioning: bicycle, swimming, aquatic exercises Gradual return to sports-specific training with optional functional brace use	General flexibility training, strengthening exercise program Power and endurance of lower extremities: diagonal and multiplanar motions with tubings, light weights, medicine balls, plyometrics Neuromuscular control, proprioceptive training Return to sports-specific participation Optional functional brace use
Criteria for advancement	Pain reduction Recovery of 90 degrees of flexion, full extension Adequate knee muscle control Tolerance for strengthening exercises	Full flexion, knee hyperextension Symmetric quadriceps and hamstring strength Symptom-free progression in a sports-specific program	No clinical symptoms Normal running and jumping mechanics Normal kinetic chain integration Completed sports-specific program

laxity compared with nonaccelerated rehabilitation, and both accelerated and nonaccelerated rehabilitation appear to have the same effect in terms of clinical assessment, satisfaction of patients, functional performance, proprioception, and isokinetic thigh muscle strength [21,22]. The use of postoperative functional bracing does not improve outcome compared with no bracing [23].

Procedures

Knee joint aspiration may be attempted in the first 24 to 48 hours after the injury to document hemarthrosis and to assist in the diagnosis. If the injured individual is not progressing in treatment because of swelling and significant limitation of motion, aspiration may be performed at later stages of treatment for symptom relief. Under sterile conditions, with a 25-gauge, 1-inch sterile disposable needle, infiltrate the skin with a local anesthetic approximately 2 cm proximal and lateral (or medial) to the patella. Follow this injection with a second injection by use of an 18-gauge, 1½-inch needle into the joint capsule. Aspirate any fluid and note the color and consistency. Without withdrawal of the needle, take off the syringe and empty it. Repeat this until all of the fluid is aspirated. Use one hand to compress the suprapatellar area to be sure all of the fluid is out before the procedure is completed.

After aspiration, icing of the knee for 15 minutes after the procedure and then for 20 minutes two or three times daily for several days is recommended.

Surgery

Surgery is indicated in patients with recurrent episodes of instability in activities of daily living and in active recreational athletes who are symptomatic and do not wish to modify their activities. Surgery is definitely indicated in the high-demand competitive athlete.

The surgical procedure of choice is the arthroscopically assisted autograft by full endoscopic or two-incision techniques, with use of either patellar bone–tendon–bone graft or four strands of hamstring tendon graft. A debate exists between the proponents of each graft source and fixation, although both seem to be fairly equal in long-term studies [24,25]. The hamstring tendon group tends to recover faster initially and to have less pain and swelling. However, although the graft strength is good, the fixation of the graft as well as the incorporation of the graft to bone seems to be weaker than with the patellar tendon [15,26,27].

The patellar tendon group, on the other hand, has better fixation and incorporation because it heals bone to bone and behaves biomechanically like a single unit; the sum of these gives it a more reproducible result, making it the preferred graft for the high-demand athlete [3,28]. The downside of its use is that it tends to produce more morbidity, such as swelling, pain, and difficulty in gaining motion initially. It also has a higher incidence of postoperative patellofemoral pain. Other grafts used are the quadriceps tendon and contralateral patellar tendon. Allograft tendon material, such as patellar tendon and tibialis anterior tendon, has also gained popularity. The advantages of these are clear and include less donor site morbidity. The disadvantages are the possibility

of disease transmission, slower graft incorporation, potential for stretching of the graft, and higher cost.

A new modality of reconstruction, the anatomic ACL reconstruction, has been popularized by Fu and coworkers [15]. This procedure tries to reconstruct both the anteromedial and the posterolateral bundles of the ACL. Fu and others have shown in vitro that this double-bundle anatomic ACL reconstruction better controls the important aspect of rotational instability of ACL deficiency. A study showed that the anatomic single- and double-bundle technique resulted in better anteroposterior and rotational stability than conventional single-bundle reconstruction [15,29,30]. The use of the ligament augmentation reconstruction system (LARS) synthetic ligament has gained popularity, with fewer graft failures and cases of synovitis compared with previous generations of synthetic grafts. However, longer follow-up studies should be undertaken to evaluate for possible complications [31].

Increased participation in competitive sports has caused an upsurge in pediatric ACL tears. The management of such injuries in the skeletally immature population is controversial. Whereas some advocate conservative management, this could cause damage to secondary structures and subsequent early osteoarthritis. Therefore surgical management has been advocated in patients with ACL deficiency returning to high-risk activities. Multiple techniques have been described in this population, including physeal-sparing, partial transphyseal, and complete transphyseal procedures. Good functional outcomes have been obtained with all techniques; however, the physeal-sparing approach has been promoted as a way to reduce the risk of growth retardation [32].

Potential Disease Complications

An untreated ACL injury can produce changes in the knee joint that may lead to significant alterations in the patient's lifestyle. The patients who continue participation in strenuous sports have recurrent episodes of pain and giving out secondary to anterior laxity and rotatory instability. These may lead to damage of associated structures, such as the menisci and other secondary restraints. A significant number of patients develop joint space narrowing with evidence of osteoarthritis. Risk factors associated with osteoarthritis after initial injury and surgical treatment include injury to the articular cartilage, meniscal tears, loss of range of motion (particularly in extension), high body mass index, and possibly arthrogenic muscle inhibition resulting in quadriceps weakness. The prevalence of radiographic knee osteoarthritis after surgical reconstruction ranges from 29% to 51%, with no statistically significant difference compared with conservative management (24%-48%). However, the prevalence of tibiofemoral osteoarthritis in isolated ACL injury has been reported to be lower (0%-13%) than in combined ACL and meniscal injuries (21%-48%), which highlights the role of meniscal injury in associated morbidity [1,11,19,33,34].

After surgical reconstruction, the incidence of ipsilateral graft tear is 5.8%; the risk of contralateral rupture is 11.8% [35]. Attention has recently been given to prevention of initial or recurrent ACL injury by modifying neuromuscular risk factors, such as muscle weakness and muscle imbalance and proprioceptive deficits, and working on sports-specific techniques, such as cutting and jumping. These programs

combine strengthening, balance, and plyometric exercises with apparent improved dynamic stability and a reduction in the incidence of injury [35–37].

Potential Treatment Complications

Medication complications include gastric, cardiovascular, and renal toxicity with nonsteroidal anti-inflammatory drugs. Injections carry the risk of infection (in approximately 1% to 2% of cases). Surgery has the risks of venous thrombosis and complications from the anesthesia. Fibrous ankylosis and significant loss of motion can be seen in the early rehabilitation stages secondary to poor progression of therapy or compliance of the patient [35].

Poor graft placement and fixation can lead to loss of motion and subsequent graft failure with recurrent instability. In patients in whom chondral lesions or meniscal tears are identified at the time of surgery, long-term sequelae include the development of arthritis even after the reconstruction [4,6,30,33,34,38].

Baker Cyst

Darren Rosenberg, DO

Joao E.D. Amadera, MD, PhD

Synonym

Popliteal cyst

ICD-9 Code

727.51 Synovial cyst of popliteal space (Baker cyst)

ICD-10 Codes

M71.20 Synovial cyst of popliteal space (Baker), unspecified knee

M71.21 Synovial cyst of popliteal space (Baker), right knee

M71.22 Synovial cyst of popliteal space (Baker), left knee

Definition

Baker cyst, the most common cyst in the posterior knee, was first described more than a century and a half ago by Adams [1] and later by Baker [2]. It affects approximately 19% of asymptomatic adults (especially adults older than 50 years) [3] and 6.3% of children [4]. It is more common in boys and in children with arthritic knees or hypermobility syndrome [5]. Two age incidence peaks exist: 4 to 7 years and 35 to 70 years [6,7]. Three factors are key to the formation of Baker cyst: (1) communication between the knee joint and popliteal bursae, (2) one-way valve effect, and (3) unequal pressure between the joint and bursae during varying angles of knee movement [7].

Chronic irritation in the knee joint may increase production of synovial fluid, which may flow from the knee joint into the bursae under higher intra-articular pressure until the one-way valve formed by the gastrocnemius-soleus complex “closes,” trapping the fluid in one of the popliteal bursae. This bursa then distends and forms a palpable mass, more commonly in the posteromedial aspect of the popliteal fossa [8]. Anatomically, the lack of supporting

structures in this area may predispose this region of the popliteal space to cyst formation [8]. Most commonly, the source of this chronic irritation is an inflammatory or degenerative joint disease, such as rheumatoid arthritis or osteoarthritis. Furthermore, conditions like infectious arthritis, polyarthritis, villonodular synovitis, connective tissue diseases, chondromalacia patellae, and persistent capsulitis are also commonly associated with Baker cysts [9,10]. In a study of 40 patients with radiographic evidence of primary osteoarthritis of the knee, 22% had Baker cyst diagnosed by ultrasonography [11]. Popliteal cysts are associated with meniscal tears in 71% to 82% of the cases, anterior cruciate ligament insufficiency in 30%, and degenerative cartilage lesions in 30% to 60% of the cases [9,10]. Noncommunicating cysts are rare in adults, often have no associated knee disease, and may be primary bursal enlargements from repeated trauma to the bursa itself related to muscle activation. Direct trauma is the most common cause of these cysts in children [4].

Symptoms

Baker cysts are often nonpainful and may be manifested as a fluctuant mass in the popliteal fossa (Fig. 64.1). Typical symptoms, if present, include swelling, pain, and stiffness exacerbated by activity such as walking. Symptoms are most readily elicited when knee flexion compresses the fluid-filled cyst, although knee extension may also cause tension on the cyst by the extended gastrocnemius-soleus muscles. The mass is often accompanied by leg swelling or diffuse calf tenderness. Numbness and tingling in the posterior aspect of the calf and plantar aspect of the foot may be present if there is neural or vascular involvement.

Physical Examination

Baker cysts are often visible or at least palpable along the medial aspect of the popliteal fossa. The cyst may be identified with the patient prone with the knee first extended and then flexed while the popliteal fossa is inspected and palpated. The round, smooth, fluctuant, and often tender cyst will be firm on palpation with knee extension and may soften or disappear with 45 degrees of knee flexion, a phenomenon known as Foucher sign [12]. The cyst can extend into the thigh or leg, or it can have multiple satellites

FIGURE 64.1 Schematic diagram of Baker cyst.

along the calf and even into the foot. These satellite cysts may or may not be connected to the primary cyst through channels. When a joint effusion accompanies the cyst, it is worthwhile to search for the source of chronic irritation. Examine the knee's range of motion, test for ligamentous laxity, and evaluate for potential patellofemoral pain and meniscal tears [9]. Furthermore, because of the proximity of the sciatic nerve and its branches to the popliteal region where cysts may be present, in rare cases nerve compression may be manifested as decreased sensation along the plantar aspect of the foot and muscle atrophy in the tibialis posterior, flexor digitorum longus, and flexor hallucis longus [13–15].

Functional Limitations

The degree of impairment produced by the cyst depends on its size and amount of tenderness. Baker cysts are usually painless and limit movement minimally, if at all, unless there is an underlying meniscal injury. However, larger cysts may be associated with moderate limitations in physical activity, particularly walking.

Diagnostic Studies

Plain films of the knee can be used to diagnose underlying degenerative joint disease but are rarely necessary to diagnose Baker cyst. Ultrasonography distinguishes solid from cystic masses and is therefore especially helpful in detecting Baker cysts when extensive joint deformities, such as those present with rheumatoid arthritis, obscure the cyst [16]. Furthermore, ultrasonography is an economical and helpful method of differentiating thrombophlebitis from Baker cysts if there is diagnostic uncertainty. Arthrography, through the injection of contrast dye into the knee joint or bursa, may clearly demonstrate the enlarged bursal structure. In addition, computed tomography may differentiate cysts from lipomas and malignant neoplasms and may show noncommunicating cysts or cysts that are not in the typical locations. Magnetic resonance imaging outlines the anatomy of the entire joint and is a sensitive test to identify Baker cyst as well as its likely cause. Magnetic resonance imaging also helps in ruling out suspected solid tumors and defining pathologic changes for possible surgical excision. On magnetic resonance imaging, Baker cysts appear as well-circumscribed masses with low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Fig. 64.2). Ultrasonography and magnetic resonance imaging are the two most common radiologic methods for evaluation of suspected Baker cysts, each with its strengths and drawbacks [17]. Testing of the erythrocyte sedimentation rate may also be helpful if an inflammatory process is suspected. In cases in which there is doubt about the cyst's etiology, analysis and culture of aspirated fluid can help differentiate between infectious, inflammatory, and mechanical processes.

Differential Diagnosis

Venous complexes
Inflammatory arthritis (rheumatoid)
Fat pads
Liposarcoma
Hematoma
Ganglionic cysts
Synovial hemangioma
Abscess
Malignant fibrous histiocytoma
Neoplasms (sarcoma, schwannoma)
Thrombophlebitis
Arterial aneurysms
Pseudothrombophlebitis
Compartment syndrome

Treatment

Initial

Intervention is needed only when a Baker cyst is symptomatic. The simplest treatment is to aspirate the fluid because aspiration collapses the cyst, and the symptoms consequently disappear. However, treatment of the cyst alone may not be adequate, and treatment of the underlying joint disease may be necessary. Ice and anti-inflammatory agents (nonsteroidal anti-inflammatory drugs) can reduce the inflammatory effusions produced by degenerative joint disease. Quadriceps strengthening exercises can be used for an associated patellofemoral syndrome. In some cases, venous sclerosants are used to prevent recurrence [12]. The cysts tend to involute spontaneously in children.

Rehabilitation

Rehabilitation may include compression and range of motion exercises as a means of decreasing swelling in addition to physical modalities (such as ice) and pharmacotherapy (such as nonsteroidal anti-inflammatory drugs, mentioned before). Furthermore, in cases of degenerative joint disease, cruciate ligament tears, and meniscal injuries, resistance exercises to maintain and to improve lower extremity muscle strength may be helpful. A comprehensive rehabilitation program may lead to progress in gait and in function to perform daily activities.

Procedures

Needle aspiration of the cyst is the most effective therapy, and provided the predisposing cause of the cyst resolves, it generally results in improvement of symptoms and function. Furthermore, if knee joint effusion is present, joint aspiration, accompanied by intra-articular corticosteroid injection, may be beneficial. In cases of noncommunicating cysts, corticosteroid injection directly into the cyst may help decrease swelling. The effect of this intervention may be followed serially through ultrasonography [18]. On the other hand, there is evidence that direct cyst infiltration with steroids has better results in patients with knee osteoarthritis compared with intra-articular injection [19].

The possibility of a vascular malformation must be eliminated either by auscultation of the mass with a stethoscope to listen for bruits or by palpation of it to feel for a pulse before cyst aspiration [20]. In addition, imaging techniques such as ultrasonography may assist in detecting cysts.

Surgery

Surgical excision is attempted only after all other methods have failed and the cyst is sufficiently large and remains symptomatic [21]. In the past, open excision was an option if the cyst remained symptomatic, but the associated recurrence rate was high (up to 63%) [22]. On occasion, surgery was necessary to correct the underlying pathologic process (e.g., arthroscopic surgery for meniscal tears or total knee replacement for intractable degenerative joint disease). Because of that, arthroscopic treatment of popliteal cysts has been the current option. Recently, the arthroscopic approach has been used to simultaneously correct both the valvular opening, by reestablishing a normal bidirectional communication, and the associated intra-articular disease responsible for the persistence of the cyst. Also, large open wounds can be avoided [23,24].

Potential Disease Complications

The most common complications of Baker cysts are dissection into the calf and rupture, leading to calf, ankle, and foot ecchymoses [12]. When the cyst ruptures, it produces a "pseudothrombophlebitis syndrome," meaning that it results in intense calf pain and swelling without associated deep venous thrombosis. Less commonly, Baker cyst produces compartment syndrome [25], peripheral neuropathy [13,14], or lower extremity claudication [26]. Rarely, if the cyst is infected, it can result in septic arthritis of the knee if an intra-articular–bursal communication exists [27]. Moreover, a possible sequela of Baker cysts may be intramuscular dissection, both distally [28] and less commonly proximally [29].

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Aspiration can result in recurrence, infection, bleeding, and neurovascular compromise. Surgery can result in local neurovascular complications and recurrence of the cysts [22,30].

M94.269 Chondromalacia, unspecified knee

Definition

Chondral injuries are any degree of loss of the normal thickness and structure of articular hyaline cartilage. Chondral damage can occur in any joint, but most of the literature has focused on the knee, which is the focus of this chapter. Outerbridge [1] classified cartilage lesions in 1961, and this remains the current classification used to date (Fig. 65.1). Partial-thickness articular cartilage injuries do not heal but are rarely associated with significant clinical symptoms [2]. Full-thickness cartilage injuries, in which the injury extends to the depth of subchondral bone, may heal in with fibrocartilage, but this type of cartilage has shown inferior biomechanical and biochemical properties compared with hyaline cartilage [2,3]. Large, full-thickness cartilage defects are less likely to benefit from the healing fibrocartilaginous response and frequently will lead to symptoms [2].

The exact incidence of acute cartilage injury is unknown. In young, active patients who present with a hemarthrosis of the knee after a traumatic event, 5% to 10% are found to have cartilage injury [4]. Many studies have retrospectively reviewed the incidence of cartilage injury after arthroscopy for other injury and found rates ranging from 5% to 11% for full-thickness lesions [5,6]. A study looking retrospectively at 25,124 arthroscopies found a 60% incidence of cartilage lesions [7]. Regarding age differences, the incidence of a localized grade III or grade IV cartilage lesion in patients undergoing arthroscopy ranged from 5% to 7% for patients younger than 40 years and 7% to 9% for patients younger than 50 years [6,7]. These studies included both acute and chronic cartilage lesions. Grade II was the most frequent lesion, seen in 42% [7]. The most common locations were the patellar articular surface (36%) and medial femoral

FIGURE 65.1 Outerbridge classification depicted by arthroscopic examples: grade I (*upper left*): cartilage softening and swelling; grade II (*upper right*): a partial-thickness defect with fissures on the surface that do not reach subchondral bone or exceed 1.5 cm in diameter; grade III (*bottom left*): fissuring to the level of subchondral bone in an area with a diameter of more than 1.5 cm; grade IV (*bottom right*): exposed subchondral bone.

condyle (34%) [7]. Seventy percent of the chondral lesions seen were associated with other injury, with medial meniscus tear (37%) and injury of the anterior cruciate ligament (36%) being the most common [7].

Most authors would agree that progression to osteoarthritis is a concern; however, there is little evidence to date that quantifies the incidence or severity of osteoarthritis after chondral injury. More natural history and outcomes research is needed to better predict a patient's likelihood of progression to symptomatic osteoarthritis according to the characteristics of the cartilage injury.

Symptoms

Patients may present with effusion, localized pain, and possible mechanical symptoms. If a full-thickness fragment has detached partially or completely, a patient may have locking or a "loose body" sensation as the fragment moves within the knee joint (Fig. 65.2). If the injury extends to subchondral bone, a hemarthrosis will be present. Some patients may have more vague symptoms without large effusion and a more generalized pain, making the diagnosis less clear.

Physical Examination

The practitioner should evaluate the patient for joint effusion and any tenderness to palpation. The patient will likely have tenderness to palpation over the anatomic region with chondral injury. The patient may have tenderness along the joint line, but more detail in examination will show that the area of maximal tenderness is over the site of chondral

FIGURE 65.2 Arthroscopic image of a free articular cartilage fragment in the suprapatellar pouch.

damage. Active and passive range of motion should be assessed. Crepitus or clunk may be present with range of motion with significant cartilage defects. It is important to perform a thorough ligamentous laxity examination to rule out any concomitant injuries [7].

Functional Limitations

The patient may have difficulty with ambulation and may walk with a limp. Activities such as climbing stairs and household chores may be limited by knee pain and swelling.

Most often, patients will be unable to return to the activity they were participating in immediately after the acute injury.

Diagnostic Studies

Plain films including standing anteroposterior, lateral, and sunrise views are obtained initially to rule out osteochondral fracture, osseous loose body, osteoarthritis, osteochondritis dissecans, and Segond fracture. Magnetic resonance imaging (MRI) is currently the standard of care in evaluating the morphology of an articular cartilage injury and can also assess for ligamentous or meniscal injuries. Even with current MRI protocols, cartilage evaluation requires expertise to characterize lesions accurately. New biochemical imaging techniques including T2 mapping, T1rho imaging, sodium MRI, and delayed gadolinium-enhanced MRI of cartilage have been used primarily for research purposes but are gaining support for their use in the clinical setting to improve detection and management of cartilage lesions [8].

Differential Diagnosis

- Meniscus tear
- Anterior cruciate ligament tear
- Osteoarthritis
- Plica syndrome
- Osteochondral fracture
- Osteochondritis dissecans

Treatment

Initial

Initial treatment is focused on pain control and resolving any effusion. Anti-inflammatories will usually suffice for pain relief. Aspiration of any effusion present will help alleviate pain and can be combined with injection of an anesthetic. Animal studies represent most of the literature on chondrolysis after intra-articular injection of anesthetic and primarily have evaluated bupivacaine toxicity [9]. However, a study using human chondrocytes has shown improved viability of chondrocytes after 0.5% ropivacaine versus 0.5% bupivacaine [9]. An intact matrix has been shown to offer a chondroprotective effect [9]. With our current knowledge of the chondrotoxicity of 0.5% bupivacaine, it should be used judiciously. A better alternative may be 0.5% ropivacaine, but longer term studies in humans are needed.

Rehabilitation

Early physical therapy is recommended to regain joint range of motion and muscle strength. Focus should be on quadriceps and hamstrings exercises. Most cartilage injuries will be associated with other injuries (e.g., anterior cruciate ligament injury), and therefore the rehabilitation protocol will vary. Numerous animal studies show an improved cartilage healing response with continuous passive motion after cartilage injury [10,11]. However, currently there are only few level III studies and no randomized controlled trials regarding this topic [12]. Nevertheless, most surgeons agree on using continuous passive motion as well as keeping

the patient non-weight bearing after cartilage restoration surgery. Patients are kept non-weight bearing ranging from 6 to 12 weeks, depending on the surgeon's protocol and any patient comorbidities.

Surgery

Most authors agree that cartilage defects to be considered for surgical treatment include full-thickness lesions (i.e., Outerbridge grade III or grade IV) larger than 2 cm² in a patient younger than 40 years [13,14]. Without taking the grade of the chondral lesion into consideration, the incidence of chondral injuries larger than 2 cm² was only 7% in one study [7]. Microfracture, osteochondral autograft transfer or transplantation (i.e., OAT), and autologous chondrocyte implantation (ACI) are the principal cartilage restoration procedures available that have been evaluated in randomized clinical trials.

Microfracture involves arthroscopic débridement of the cartilage lesion to stable squared off edges. The zone of calcified cartilage is removed, and cortical penetration with an awl is performed, allowing medullary bleeding and clot formation [13] (Fig. 65.3). Osteochondral autograft transplantation or mosaicplasty involves harvesting of viable, structurally intact cartilage and bone plugs from a “dispensable” portion of a joint and transplanting the autograft to the chondral defect. ACI involves the harvest of chondrocytes from a nonessential portion of the knee during the first-stage surgery. The specimen undergoes expansion of chondrocytes in a laboratory. The chondrocytes are then placed in a medium, which is implanted on the defect with an overlying periosteal patch or collagen scaffold during the second-stage surgery. Given limitations of available comparative studies, no clear outcome benefit can be confirmed for either OAT or ACI over microfracture [13,15]. Only one level I study indicates better outcomes in athletes with initial arthroscopic OAT versus microfracture [16]. For cartilage lesions larger than 2 cm², Gudas and colleagues [16] showed worse clinical outcomes with microfracture. Currently, the literature lacks any level I study with a natural history control

FIGURE 65.3 Arthroscopic image of the microfracture technique showing medullary bleeding after cortical penetration with an awl.

group, which makes outcomes after current surgical procedures difficult to interpret. With lack of superiority of any one surgical treatment, microfracture has been considered the first-line therapy, given its technical ease, lack of donor site graft morbidity, and affordability [13,15].

Potential Disease Complications

Most clinicians assume that traumatic articular cartilage lesions will continue to progress to osteoarthritis. However, the true natural history of these lesions has yet to be formally studied and remains unknown. Messner and Maletius [17] looked at radiographs 14 years after diagnosis of severe chondral injury in 28 patients to find that 22 had joint space narrowing of less than 50% in the compartment with injury.

Potential Treatment Complications

Common complications encountered after cartilage restoration surgery include arthrofibrosis, superficial wound infections, and tissue hypertrophy [15]. Lower incidences of deep venous thrombosis, hemarthrosis, and graft malpositioning occur [15]. Arthrofibrosis appears to occur with equal frequency with microfracture, ACI, and the OAT procedure [15]. Tissue hypertrophy surrounding the lesion and reactive synovitis are associated more commonly with ACI [15]. Proud or recessed graft is limited to the OAT procedure [15]. Reoperation is another complication and appears to be higher with ACI versus microfracture [15,18]. Newer all-arthroscopic, second-generation ACI techniques with a collagen membrane patch may show lower reoperation rates and decreased arthrofibrosis over the first-generation periosteal ACI techniques [18].

Collateral Ligament Sprain

Paul Lento, MD
Venu Akuthota, MD

Synonyms

Knee ligamentous injuries
Medial or lateral collateral knee injury
Knee valgus or varus instability or insufficiency

ICD-9 Codes

- 717.81 Old disruption of lateral collateral ligament
- 717.82 Old disruption of medial collateral ligament
- 844.0 Sprains and strains of knee and leg (lateral collateral ligament)
- 844.1 Sprains and strains of knee and leg (medial collateral ligament)

ICD-10 Codes

- M23.641 Spontaneous disruption of lateral collateral ligament of right knee
- M23.642 Spontaneous disruption of lateral collateral ligament of left knee
- M23.649 Spontaneous disruption of lateral collateral ligament of unspecified knee
- M23.631 Spontaneous disruption of medial collateral ligament of right knee
- M23.632 Spontaneous disruption of medial collateral ligament of left knee
- M23.639 Spontaneous disruption of medial collateral ligament of unspecified knee
- S83.421 Sprain of lateral collateral ligament of right knee
- S83.422 Sprain of lateral collateral ligament of left knee

- S83.429 Sprain of lateral collateral ligament of unspecified knee
 - S83.411 Sprain of medial collateral ligament of right knee
 - S83.412 Sprain of medial collateral ligament of left knee
 - S83.419 Sprain of medial collateral ligament of unspecified knee
- Add seventh character for episode of care

Definition

The medial collateral ligament (MCL) and lateral collateral ligament (LCL) are important structures that predominantly prevent valgus and varus forces, respectively, through the knee (Fig. 66.1). Like other ligamentous injuries, knee collateral ligament sprains can be defined by three grades of injury. With a grade I sprain, there is localized tenderness without frank laxity. Anatomically, only a minimal number of fibers are torn. On physical examination, the joint space opens less than 5mm (i.e., 1+ laxity). With a moderate, or grade II, sprain, there is more generalized tenderness without frank laxity. Grade II sprains can cover the gamut from a few fibers torn to nearly all fibers torn [1]. The joint may gap 5 to 10mm (i.e., 2+ laxity) when force is applied. A severe, or grade III, sprain, by definition, is a complete disruption of all ligamentous fibers with a joint space gap of more than 10mm (i.e., 3+ laxity) on stressing of the ligament [2].

Medial Complex Injury and Resultant Instability

The MCL is the most commonly injured ligament of the knee [3]. In fact, injury to this structure has been estimated to occur in 0.24 per 1000 people in the United States in any given year and to be twice as high in males (0.36) compared with females (0.18) [4]. This ligament is usually injured when valgus forces are applied to the knee [5]. Contact injuries produce grade III MCL deficits; noncontact MCL injuries typically result in lower grade injuries. Although MCL injury can occur in isolation, valgus forces typically instigate injury to other medial structures [6]. Findings of a rotational component to medial joint instability should prompt

FIGURE 66.1 Medial and lateral collateral ligaments.

a search for cruciate ligament, meniscal, or posterior oblique ligament involvement [7,8].

Lateral Complex Injury and Resultant Instability

The LCL is much less frequently injured than the MCL. True isolated injury to the LCL is rare. True straight lateral instability requires a large vector force. Thus, a complete knee dislocation with possible damage to neurovascular structures should be suspected if straight lateral instability is present [9]. Posterolateral rotatory instability appears to be a more frequent cause of lateral instability than of straight lateral instability. Most authors believe that posterolateral rotatory instability requires disruption of the arcuate complex, the posterior cruciate ligament, and the LCL. The usual mechanism of posterolateral rotatory instability is forcing of the knee into hyperextension and external rotation [6,9].

Symptoms

Medial or lateral knee pain is the most common symptom related to knee collateral ligament injury. Interestingly, grade I and grade II injuries cause more pain than grade III injuries do [3,10]. Pain is often accompanied by a sensation of knee locking [8]. This may be due to hamstring muscle contraction or concomitant meniscal injury. Patients may also report an audible pop, although this is more common with anterior cruciate ligament injuries [3]. A giving way sensation or a feeling of instability is often reported with high-grade injuries. Moreover, patients with high-grade injuries may also have neurovascular damage [11]. Therefore these individuals may complain of a loss of sensation or muscle strength below the level of the knee [9].

Physical Examination

Physical examination begins with the uninjured knee to obtain a baseline. Palpatory examination can be as important as ligamentous laxity testing. Palpation can reveal tenderness along the length of the collateral ligament, localized swelling, or a tissue defect [8]. Localized swelling correlates well with the area of injury to the MCL [10]. With pure joint line tenderness, an underlying meniscal injury should be suspected. A true knee joint effusion may also be present with collateral ligament injuries; however, it is more prevalent with meniscal or cruciate ligament injury [12].

Laxity of the medial joint ligaments is determined by the abduction stress test (Fig. 66.2A), performed by examination of the knee at 0 and 30 degrees of joint flexion. If the test result is negative, a firm endpoint will be reached. If the test result is grossly positive, the femur and tibia will gap with valgus stress and “clunk” back when the stress is removed [13]. Although it is controversial, increased medial joint laxity of the fully extended knee with a valgus force not only implies damage to the superficial and deep fibers of the MCL but also indicates rupture of the posterior cruciate ligament or posterior oblique ligament [14–16]. If laxity occurs at 30 degrees of flexion but not at 0 degrees, one may confidently conclude that MCL injury is present with sparing of the posterior capsule and posterior cruciate ligament [10,13]. The soft endpoint during valgus stress with the knee at 30 degrees of flexion is the intact cruciate ligament [16]. Although the anterior drawer test is classically used for chronic anterior

FIGURE 66.2 A, Abduction stress of the knee at 30 degrees tests for medial collateral ligament injury. B, Adduction stress of the knee at 30 degrees tests for lateral collateral ligament injury. (From Mellion MB, Walsh WM, Shelton GL. *The Team Physician's Handbook*, 2nd ed. Philadelphia, Hanley & Belfus, 1997.)

cruciate ligament tears, it can be a useful adjunctive test for detection of MCL or posterior oblique ligament injury [10].

Laxity of the lateral knee joint ligaments is determined by the adduction stress test, which is also performed at 0 and 30 degrees of knee flexion and compared with the opposite “normal” knee (Fig. 66.2B). Gapping of the lateral joint line at 30 degrees of knee flexion indicates damage to the LCL and arcuate ligament complex [12,15]. However, joint opening with the knee in full extension indicates damage not only to the LCL but also to the middle third of the capsular ligament, cruciate ligaments, iliotibial band, or arcuate ligament complex [6,17]. When LCL injury is associated with rotational instability, the reverse pivot shift may be helpful [18]. This maneuver is performed by application of a varus force to an initially flexed knee. A positive test result reveals a clunk as the knee is passively extended from a flexed position. The clunk is a result of the relocation with extension of a knee subluxed in flexion [11,15]. Rotational instability may also be detected by the external rotation recurvatum test (Fig. 66.3).

FIGURE 66.3 External rotation recurvatum test. Both knees are passively held in extension by holding the forefoot. If the tibia on the affected side externally rotates more than the normal side, the test result is considered positive and indicates damage to the posterolateral knee structures.

Functional Limitations

The functional limitations for patients with MCL and LCL injuries result from instability. In general, sagittal plane movements are better tolerated than frontal or transverse plane motions. Most patients with grade III tears of the MCL are able to walk comfortably without an assistive device. Few, however, are able to traverse steps or to do a full knee squat [10]. Patients may also report difficulty with transfers and “cutting” sports activities. Some individuals with posterolateral ligament injuries may have pain with prolonged standing or knee hyperextension. This posterolateral laxity may eventually result in significant genu recurvatum as well as tibia vara, producing pain with even basic activities such as walking and standing [6].

Diagnostic Testing

Plain radiographs are usually normal in acute sprains of the collateral ligaments. Radiographs may be particularly useful to detect avulsion and tibial plateau fractures [7]. For example, an avulsion fracture of the proximal fibula can be detected after a varus-type injury and is associated with posterolateral corner injury, the so-called arcuate sign [19]. Stress views may be indicated in skeletally immature patients for evaluation of physeal injuries [20]. The current “gold standard” diagnostic test is magnetic resonance imaging. Magnetic resonance imaging can detect concomitant injury as well as the severity of collateral ligament damage [21]. Bone bruises not evident on plain films may be detected by magnetic resonance imaging. This can be an important finding, particularly in patients who are experiencing persistent pain. Diagnostic musculoskeletal ultrasound has been used to diagnose and prognosticate injuries of the collateral ligaments and posterolateral corner of the knee [22–24].

Differential Diagnosis

MEDIAL KNEE PAIN

- Medial meniscus injury
- Anterior cruciate ligament injury
- Medial compartment osteoarthritis
- Pes anserine bursitis
- Medial tibial plateau fracture
- Vastus medialis obliquus injury
- Medial plica band syndrome

MEDIAL OR LATERAL KNEE PAIN

- Patella subluxation or dislocation
- Bone bruise
- Osteochondral injury
- Referred or radicular pain

LATERAL KNEE PAIN

- Lateral meniscus tear
- Iliotibial band syndrome
- Lateral compartment osteoarthritis
- Popliteus or biceps tendinitis
- Lateral gastrocnemius strain

Treatment

Initial

After it has been determined whether concomitant injury is present, all grades of collateral ligament injuries are treated initially in the same manner. The basic principles of PRICE (*protect, rest, ice, compression, elevation*) apply. Immobilization can be used if pain is a significant issue but typically only for a limited time in grade II MCL and LCL injuries [25]. Alternatively, patients with grade II and grade III injuries may need crutches or a hinged knee brace locked between 20 and 60 degrees to provide additional support for an unstable knee, but there is no consensus regarding this [26]. Allowable brace range of motion is increased as tolerated to prevent arthrofibrosis [7,12,27]. Nonsteroidal anti-inflammatory medications may be prescribed to provide pain relief as well as to reduce local inflammation associated with acute injury [28].

Rehabilitation

The goals of rehabilitation for the knee with a collateral ligament injury are to restore range of motion, to increase stability, and to return pain-free activity. Rehabilitation protocols have been described even for grade III MCL injuries [25]. Within the first 24 to 48 hours after injury, static isometric quadriceps contractions and electrical stimulation can be instituted to reduce local tissue swelling and to retard muscle atrophy [13,27]. Range of motion exercises and gentle stretching activities are introduced after the first day [7]. Early weight bearing is also encouraged. Aerobic conditioning can be maintained by use of upper body ergometry, stationary bicycle, or swimming with gentle flutter kicks. Maintenance-phase rehabilitation should emphasize exercise in multiple planes. Rehabilitation should eventually progress to functional or sport-specific activity [25]. A combination of closed and open kinetic chain exercises is used [25,29]. Typically, individuals with mild collateral ligament injuries return to activity after 3 to 4 weeks; patients with grade II and grade III injuries may be able to return to activity after 8 to 12 weeks [30]. Prophylactic hinged knee brace use has been advocated, although effectiveness remains controversial [31–33]. Postsurgical rehabilitation for grade III LCL and MCL injuries with concomitant anterior cruciate ligament, posterior cruciate ligament, or meniscal repair should be at the discretion of the individual surgeon. Variability occurs with each surgeon in respect to immediate weight bearing, protected range of motion, and return to full activity [34].

Procedures

Procedures such as corticosteroid injections have not been studied in acute collateral ligament injuries and typically are not indicated [35]. Needling of symptomatic calcifications within the MCL has been reported [36].

Surgery

The treatment of grade I and grade II injuries of the MCL and LCL is nonsurgical. Grade III injuries, especially when they are associated with concomitant injuries, may be

treated surgically. However, most practitioners treat isolated grade III MCL injuries nonsurgically secondary to the high healing rates [3,13,27,37]. Repair of an MCL tear without repair of an associated anterior cruciate ligament injury may lead to a high failure rate [8]. In contrast, grade III LCL injuries or posterolateral complex tears with or without associated cruciate ligament injuries have been shown to heal poorly with nonsurgical measures [7,38,39]. In this case, surgical intervention within 2 weeks, addressing deficits of the arcuate ligament complex, lateral meniscus, and cruciates, provides optimal outcomes [7].

Potential Disease Complications

The most significant disease complication is chronic knee instability. This most commonly occurs with undetected injury to the posterolateral joint complex. Another cited complication is an increased risk of osteoarthritis. Osteoarthritis occurs more frequently with combined MCL and anterior cruciate ligament ruptures than with pure MCL injury [40]. Pellegrini-Stieda disease may also be a rare complication [41]. This condition consists of focal calcium deposition in the area of the injured ligament, typically on the femoral insertion of the MCL. Massage or manipulation may worsen this condition. Instead, calcium reabsorption may be stimulated by dry needling [7,12,36].

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. If the injured knee is immobilized for too long or if range of motion does not proceed in an appropriate fashion, stiffness may result with possible loss of full extension. Similarly, if a surgeon reattaches the deep or superficial components of the MCL to the femoral condyle as opposed to the epicondyle, ankylosis of the joint may result, restricting flexion as well as extension [8].

CHAPTER 67

Compartment Syndrome of the Leg

Joseph E. Herrera, DO
Mahmud M. Ibrahim, MD

Synonyms

Acute compartment syndrome
Volkmann ischemia
Traumatic tension in muscles
Calf hypertension
Well leg compartment syndrome
Chronic compartment syndrome
Chronic exertional compartment syndrome
Exercise-induced compartment syndrome
Anterior or medial tibial pain syndrome

ICD-9 Codes

728.9 Unspecified disorder of muscle, ligament, and fascia
958.8 Other early complications of trauma (compartment syndrome)

ICD-10 Codes

M62.9 Disorder of muscle, unspecified
T79.A0 Compartment syndrome, unspecified

Definition

Compartment syndrome can be either an acute or chronic condition caused by increased tissue pressure within an enclosed fascial space. The focus of this chapter is compartment syndrome of the leg, although it can also affect the thighs or upper extremities.

Acute Compartment Syndrome

Acute compartment syndrome (ACS) is a serious condition caused by a rapid rise in pressure in an enclosed space,

which can lead to necrosis of the muscles and nerves in the involved compartment. Untreated, ACS can progress to contractures, paralysis, infection, and gangrene in the limb as well as systemic problems, such as myoglobinuria and kidney failure [1]. ACS, most commonly occurring in males younger than 35 years, is most often caused by trauma such as fractures, crush injuries, muscle rupture, direct blow to a muscle, and circumferential burns. Direct pressure from a cast or antishock garment can increase the risk for compartment syndrome [2]. ACS can occur in as many as 17% of tibial fractures [3]. The anterior compartment is most commonly affected, although multiple compartments are often involved.

Nontraumatic causes of ACS are more rare. These include hemorrhage into a compartment, as can occur in anticoagulated patients [2], and compartment syndrome after diabetic muscle infarction [4]. In patients with decreased mental status with prolonged limb compression, such as with alcohol or drug abuse, ACS can also develop from soft tissue injury and swelling [5].

Another nontraumatic cause of compartment syndrome is ischemia and then hyperperfusion caused by prolonged surgery in the lithotomy position. This is also known as well leg compartment syndrome and is most often seen after pelvic and perineal surgery. Risk factors include the length of the procedure, the amount of leg elevation, the amount of perioperative blood loss, and the presence of peripheral vascular disease and obesity. The overall incidence in complex pelvic surgeries may be as high as 1 in 500 [6].

Chronic Compartment Syndrome

Chronic compartment syndrome (CCS) occurs when the fascia in the lower leg does not accommodate to the increase in blood flow and fluid shifts that may occur with heavy exercise [7]. An increase in compartmental pressure then interferes with blood flow, leading to ischemia and pain when the metabolic demands cannot be met [8]. The risk of CCS is increased by anabolic steroids, which can induce muscle hypertrophy, thereby causing an increase in intracompartmental pressure and decreasing fascial elasticity [9]. CCS is most commonly seen in runners [10], cyclists, and other athletes in sports that demand running, jumping, and cutting,

such as basketball and soccer. The true incidence is unknown as most people suffering from early symptoms will decrease or modify their activity [11]. With normal physical activity, muscle volume can increase up to 20% [12]. The anterior compartment is most commonly involved, followed by the deep posterior compartment [11].

Symptoms

The area in which symptoms occur and the type of complaints depend on which compartment is involved.

Acute Compartment Syndrome

Patients may present with pain out of proportion to the injury and swelling or tenseness in the area. Other symptoms include severe pain with passive movement of the muscles within the compartment, loss of voluntary movement of the muscles involved, and sensory changes and paresthesias in the area supplied by the nerve involved [3,7]. The classic findings associated with arterial insufficiency are often described as signs of ACS, but this is incorrect. Of the five classic signs (pain, pallor, pulselessness, paresthesias, paralysis), only pain is commonly associated with compartment syndrome, particularly in its early stages [12].

Chronic Compartment Syndrome

In CCS, pain has a gradual onset that usually coincides with an increase in exercise training load or training on hard surfaces. It is described as aching, burning, or cramping and occurs with repetitive movements in a specific muscle region. The pain usually occurs around the same time each time the patient participates in the activity (e.g., after 15 minutes of running) and increases or stays constant if the activity continues. The pain disappears or dramatically lessens after a few minutes of rest. Symptoms can occur bilaterally [8].

As symptoms progress, a dull aching pain may persist. Pain may be localized to a particular compartment, although multiple compartments can often be involved. Numbness and tingling may occur in the nerves that travel within the involved lower limb compartment. CCS can be seen with other overuse syndromes (e.g., concurrent with tibial stress fractures).

Physical Examination

The examination is focused on the following four compartments of the leg (Fig. 67.1).

Anterior compartment contains the tibialis anterior, which dorsiflexes the ankle; the long toe extensors, which dorsiflex the toes; the anterior tibial artery; and the deep peroneal nerve, which supplies sensation to the first web space.

Lateral compartment contains the peroneus longus and brevis, which evert the foot, and the superficial peroneal nerve, which supplies sensation to the dorsum of the foot.

Superficial posterior compartment contains the gastrocnemius and soleus muscles, which plantar flex the foot, and part of the sural nerve, which supplies sensation to the lateral foot and distal calf [1,8,12].

FIGURE 67.1 The focus of the physical examination in compartment syndrome is the anterior, lateral, superficial posterior, and deep posterior compartments.

Deep posterior compartment contains the tibialis posterior, which plantar flexes and inverts the foot; the long toe flexors, which plantar flex the toes; the peroneal artery; and the tibial nerve, which supplies sensation to the plantar surface of the foot. This compartment may contain several subcompartments [13].

Acute Compartment Syndrome

In ACS, inspection reveals a swollen, tense limb. Motor testing reveals weakness or paralysis of the muscles involved in the affected compartment. Sensory testing may show numbness in the area supplied by the nerve involved in the affected compartment. Two-point discrimination is a better diagnostic test for compartment syndrome than pinprick [13]. Pulses and capillary refills are generally normal as these are involved only with extremely high pressures [3,7,14,15].

Chronic Compartment Syndrome

In CCS, inspection is usually unremarkable, but fascial defects have been observed in up to 40% of individuals. These defects may represent the body's attempt to accomplish an autorelease [11]. Palpation of the affected area will reveal a firm compartment and tender muscle group. There may also be tenderness along the posteromedial surface of the tibia [16]. In approximately 40% of cases, muscle herniation in the compartment can be palpated, especially in the anterior and lateral compartments where the superficial peroneal nerve pierces the fascia [6]. In severe cases, sensory testing will show numbness in the area supplied by the nerve involved, but this is usually normal at rest [7]. Motor testing may reveal weakness, depending on the compartment involved: dorsiflexion weakness if the anterior compartment is involved, foot eversion weakness if the lateral compartment is involved, and plantar flexion weakness if one of the posterior compartments is involved. Pain is reproduced by repetitive activity, such as toe raises, or running in place. Compartment syndrome occurs more commonly in patients who pronate during running; thus, pronation is a common finding on physical examination [1,7,17].

Functional Limitations

Acute Compartment Syndrome

The sequelae of ACS may be nerve and muscle injury with resulting footdrop, severe muscle weakness, and contractures. This can lead to an abnormal gait and all the limitations that this can cause, including difficulties with stairs, sports participation, and activities of daily living. In addition, it can lead to muscle necrosis, thereby causing long-term disability [18].

Chronic Compartment Syndrome

With CCS, functional limitations usually occur around the same point each time during exercise, at that individual's ischemic threshold. For example, symptoms may start to develop each time a runner reaches the half-mile mark or each time a cyclist climbs a large hill. This may significantly limit sports participation and occasionally even interferes with activities of daily living, such as prolonged walking.

Diagnostic Studies

Compartmental tissue pressure measurement is the “gold standard” for diagnosis. The devices most commonly used to measure intracompartmental pressures were traditionally the slit and wick catheters (Fig. 67.2) [7]. Newer devices, such as the transducer-tipped probe (Fig. 67.3), are now gaining popularity [19]. Ultrasound-guided transducer placement is especially helpful in patients receiving anticoagulation, patients with a large body habitus, and patients with distorted anatomy, such as after surgery or trauma [11].

Acute Compartment Syndrome

Normal compartment pressure is less than 10mm Hg. Traditionally, absolute tissue pressure above 30mm Hg

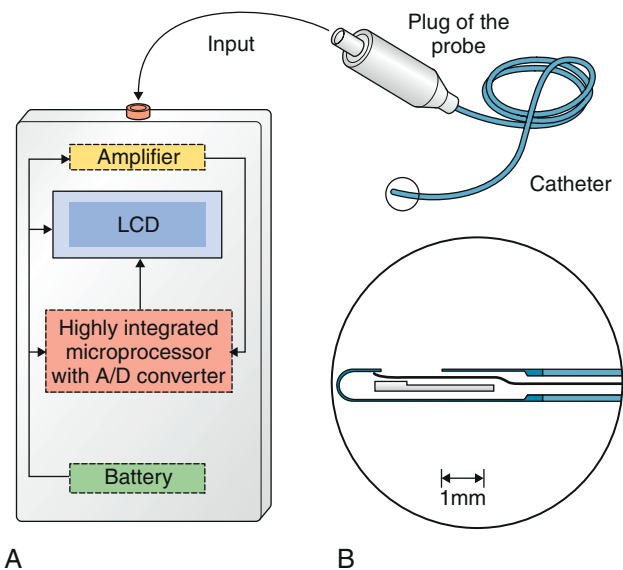

FIGURE 67.3 Transducer-tipped probe. **A**, Hand-held device. **B**, Catheter tip with pressure-sensing mechanics. (From Willy C, Gerngross H, Sterk J. Measurement of intracompartmental pressure with use of a new electronic transducer-tipped catheter system. *J Bone Joint Surg Am* 1999;81:158-168.)

was considered the cutoff value for fasciotomy to be performed [7,19]. However, it is likely that many unnecessary fasciotomies were performed by use of this measure alone. Currently, continuous monitoring of compartment pressures is used in high-risk cases, such as leg trauma with tibial fractures. The differential pressure, calculated as the intramuscular pressure subtracted from the diastolic blood pressure, determines the treatment course. If the differential pressure is less than 30mm Hg, fasciotomy is indicated [20]. Studies have shown that if this differential pressure remains consistently above 30mm Hg, even with markedly

FIGURE 67.2 Compartmental tissue pressure measurements for the diagnosis of compartment syndrome with the use of slit and wick catheters.

elevated tissue pressures, patients have excellent clinical outcomes and fasciotomy is not necessary [20,21].

Because of the invasive nature of compartmental pressure measurements, other diagnostic tools have been sought. Magnetic resonance imaging may be helpful in making the diagnosis. Magnetic resonance imaging findings may include loss of normal muscle architecture on T1-weighted images, edema within the compartment, and strong enhancement of the affected compartment with the contrast agent gadolinium-DTPA [22].

Chronic Compartment Syndrome

For CCS, absolute pressure measurements obtained at rest, during exercise, and after exercise are used to make the diagnosis. Interestingly, there does not seem to be a particular threshold compartmental pressure at which symptoms occur, and patients with higher pressures do not necessarily have worse symptoms than those of patients with less abnormal pressures [23]. The average time from the onset of symptoms to the time that the diagnosis is made is 22 months [7].

The following is one set of values [7,15] commonly used to diagnose *anterior compartment syndrome*:

- Pre-exercise pressure >15 mm Hg
- 1 minute after exercise >30 mm Hg
- 5 minutes after exercise >20 mm Hg

It is important that the patient's symptoms correlate with the compartment in which there is elevated pressure. Pressure should increase in the symptomatic compartment with exercise and remain elevated for an abnormal time [8,23]. Values for *posterior compartments* are more controversial. Normal resting pressures are less than 10 mm Hg, and values should return to resting levels after 1 to 2 minutes of exercise [15].

Drawbacks to measurement of pressures include the following:

- They are invasive and can be complicated by bleeding or infection.
- Because of the anatomy, it is difficult to test the deep posterior compartment.
- Pressures are dependent on the position of the leg and the technique used, so strict standards should be followed.
- It is time-consuming because each compartment must be tested separately, and all compartments should be tested because multiple areas are often involved.
- It is often difficult for patients to exercise with the catheter in place [17,24].

Because of these drawbacks, alternative tests to confirm the diagnosis are sometimes used. Magnetic resonance imaging done before and after exercise can show increased signal intensity throughout the affected compartment in the T2-weighted images after exercise in patients with compartment syndrome [25,26]. Alternatively, near-infrared spectroscopy has been used as well. This method measures the hemoglobin saturation of tissues [9]. In cases of CCS, there is deoxygenation of muscle during exercise and delayed reoxygenation after exercise. Failure of the compartment to return to baseline within 25 minutes after exercise is diagnostic of CCS [11]. Although near-infrared spectroscopy seems to be helpful in patients with anterior compartment syndrome, light absorption may be altered in

deeper compartments, and therefore it is more difficult to monitor the pressure in these deeper compartments [9]. Other methods include thallium stress testing and nuclear magnetic resonance spectroscopy, which may also be helpful in the diagnosis of CCS [9]. Triple-phase bone scan and single-photon emission computed tomography scans can be used to rule out other conditions in the differential diagnosis, such as medial tibial stress syndrome or stress fractures [11].

Differential Diagnosis

ACUTE COMPARTMENT SYNDROME

Arterial occlusion
Severe muscle trauma
Neurapraxia of the common, deep, or superficial peroneal or tibial nerve
Deep venous thrombosis
Cellulitis
Fracture

CHRONIC COMPARTMENT SYNDROME

Tibial or fibular stress fractures
Shin splints
Atherosclerosis with vascular claudication
Popliteal artery compression from aberrant insertion of the medial gastrocnemius
Muscle hyperdevelopment causing compression of the popliteal artery
Cystic adventitial disease [27]

Treatment

Initial

Acute Compartment Syndrome

If the differential pressure is less than 30 mm Hg, treatment of ACS is surgical fasciotomy, which is described later [20]. In cases in which the differential pressure remains above 30 mm Hg, it has been shown to be safe to observe those patients with serial pressure measurements [21].

Chronic Compartment Syndrome

For CCS, the initial treatment consists of rest, ice, and non-steroidal anti-inflammatory drugs. Counseling the patient to avoid running on hard surfaces, to use orthotics to control pronation, and to wear running shoes with the appropriate amount of cushion and a flared heel is important [7]. Surgery is usually reserved for symptoms persisting beyond 6 to 12 weeks, despite conservative therapy [13].

Rehabilitation

Acute Compartment Syndrome

The rehabilitation of ACS is limited to the postfasciotomy stage. Rehabilitation depends on the extent of the injury. Proper skin care for either the open area left to close by secondary intent or the skin grafts that have been applied is imperative. An ankle-foot orthotic to correct footdrop is often needed. Physical therapy is needed for gentle range of motion exercises to prevent contractures and should begin as soon after surgery as possible and as allowed by

wound healing issues. Other measures include strengthening of muscles that may be only partially affected and gait training, possibly with an assistive device. There is no scientific literature to support any specific rehabilitation protocols, and so programs should be individualized on the basis of the particular patient's needs. If the patient has deficits in activities of daily living, such as dressing or transfers, occupational therapy may be helpful in addressing these areas.

Chronic Compartment Syndrome

Controversy exists about the success of conservative treatment of CCS [7]. Current recommendations are based on the initial use of PRICE (*protection, rest, ice, compression, and elevation*), with progression to reestablishing range of motion and soft tissue mobility, incorporating stretching, nerve gliding techniques, strengthening exercises, and incorporating biomechanical analysis of the patient during sport-specific activity [28]. Evaluating and identifying the underlying cause, such as excessive pronation, is important in considering the rehabilitation course. Treatment of excessive pronation includes establishing normal muscle lengths throughout the kinetic chain, especially stretching the gastrocnemius and posterior tibialis, and strengthening the anterior tibialis [29]. Shoe orthoses to address excessive pronation may also be helpful. Training errors, such as rapid increases in intensity or duration, are addressed and corrected. In addition, soft tissue mobilization and manipulation techniques, including massage, myofascial stretching, and taping, may increase fascial compliance. This would address the proposed pathophysiologic process involving increased fascial thickness, stiffness, and increased pressure [28].

If fasciotomy is done for CCS, postsurgical rehabilitation should follow. Weight bearing is permitted as tolerated, and gentle range of motion exercises are begun 1 to 2 days postoperatively. Strengthening and gradual return to activity begin at 1 to 2 weeks. Full return to activity such as running usually takes 8 to 12 weeks [30].

Procedures

Procedures are not typically done in compartment syndrome except as stated earlier to measure compartmental pressures as a diagnostic procedure.

Surgery

Acute Compartment Syndrome

Fasciotomy should be performed for ACS as soon as possible. Large longitudinal incisions are made in the affected compartment. These incisions are left open to be closed gradually, or split-thickness skin grafts are applied. Results of the surgery are variable and depend on the length of time of ischemia and other injuries involved [31]. Newer techniques allow fasciotomy to be performed with endoscopy and minimally invasive incisions [11,13]. Controversy exists as to whether all four compartments need to be released in cases of ACS. One study showed that release of only the anterior compartment had equivalent results to release of the anterior and lateral compartments [32]. If treatment is delayed for more than 12 hours, it is

assumed that permanent damage has occurred to the muscles and nerves in the involved compartment. Late reconstruction procedures can be done, if necessary, to correct muscle contractures or to perform tendon transfers for footdrop [31].

Chronic Compartment Syndrome

Fasciotomy is also the mainstay for surgical treatment of CCS [7]. Different techniques for fasciotomy have been described. Most consist of making a small incision in the skin and then releasing the fascia as far proximally and distally as possible while avoiding nerves and vessels. Results of surgery are usually good, with average success rates of 80% to 90% as defined by a decrease in symptoms and a return to sports [30].

Potential Disease Complications

Acute Compartment Syndrome

In ACS, ischemia of less than 4 hours usually does not cause permanent damage. If ischemia lasts more than 12 hours, severe damage is expected. Ischemia of 4 to 12 hours can also cause significant damage, including muscle necrosis, muscle contractures, loss of nerve function, infection, gangrene, myoglobinuria, and renal failure. Amputation of the affected limb is sometimes necessary, and even death may occur from the systemic effects of necrosis or infection [1,3,7]. Recurrence has also been known to develop. Calcific myonecrosis can also be a late side effect [33].

Chronic Compartment Syndrome

If CCS is left untreated, it may become acute in presentation and result in irreversible sequelae [13].

Potential Treatment Complications

ACS fasciotomy has serious complications. Mortality rates are 11% to 15%, and serious morbidity is common, including amputation rates of 10% to 20% and diminished limb function in 27% [34].

CCS fasciotomy is a less extensive surgery on a healthier population. Complications are uncommon but can include bleeding, infection, deep venous thrombosis, wound infection, lymphocele, and nerve injury, particularly to the superficial peroneal nerve. Case series report a recurrence rate of 3% to 20%. The most common reasons for recurrence are excessive scar tissue formation, causing the compartment to become tight again, and inadequate fascial release. A case series exploring the outcome of repeated fasciotomy for recurrence of symptoms reported that 70% of patients had good or excellent outcomes [35].

One potential long-term complication of fasciotomy is an increased risk for development of chronic venous insufficiency caused by the loss of the calf musculovenous pump [36].

CHAPTER 68

Hamstring Strain

Omar M. Bhatti, MD

Beth M. Weinman, DO

Anne Z. Hoch, DO

Synonyms

Hamstring contusion

Hamstring pull

Hamstring tear

Hamstring avulsion

Delayed-onset muscle soreness of the posterior thigh

Stretch-induced injury to the hamstring

ICD-9 Codes

843.8 Sprains and strains of hip and thigh, other specified site

843.9 Sprains and strains of hip and thigh, unspecified site

ICD-10 Codes

S73.101 Unspecified sprain of right hip

S73.102 Unspecified sprain of left hip

S73.109 Unspecified sprain of unspecified hip

Definition

Hamstring strains are among the most common muscle injuries, particularly in athletes. Hamstring strains increase in incidence with age and are most common in football, soccer, and sports that require sprinting. The hamstrings consist of three muscles: the semimembranosus and semitendinosus muscles medially and the long and short heads of the biceps femoris muscle laterally.

Hamstring strains constitute a range of injuries from delayed-onset muscle soreness to partial tears to complete rupture of the muscle-tendon unit [1]. Injuries can occur

from direct or indirect forces. Direct forces refer to lacerations and contusions. Complete avulsion of the proximal hamstring origin from the ischial tuberosity has been described, most commonly in water-skiers [2,3]. These injuries occur when forced hip flexion is sustained while the knee remains in complete extension.

Most hamstring injuries, however, occur from indirect forces with exertional use of the muscles, such as running, sprinting, and hurdling. Most hamstring injuries occur at the myotendinous junction during eccentric actions when the muscle lengthens while developing force, most commonly in the lateral hamstrings [4]. The biceps femoris has two heads with different origins and dual innervation and is therefore considered a “hybrid” muscle [5]. Dyssynergic contraction of the muscles is one of many proposed etiologic factors predisposing the hamstrings to strain. Other proposed etiologic factors include the hamstring’s being a two-joint muscle, insufficient hamstring flexibility (Fig. 68.1), insufficient warm-up and stretching before activity, strength imbalance between the hamstrings and quadriceps, strength imbalances between the right and left hamstrings, previous injury to the hamstring, higher running speeds, and poor strength or endurance of the hamstrings. Hamstring strains can occur in a variety of patients from young to old and in any level of athletics from the “weekend warrior” to the elite athlete.

The hamstrings function over two joints. Like other biarticular muscle groups, such as the quadriceps femoris, the gastrocnemius, and the biceps brachii, the hamstrings are more susceptible to injury. The hamstrings cross the hip and knee joint (with the exception of the short head of the biceps femoris). During the latter part of the swing phase of gait, the hamstrings act eccentrically to decelerate knee extension; and at heel strike, the hamstrings act concentrically to extend the hip. During running, this rapid change in function puts the muscle at risk for injury; the higher the running speed and angular velocity, the greater the forces at heel strike [6,7]. Any large strength imbalance between the larger and stronger quadriceps and the hamstrings will put the hamstrings at a disadvantage. If the synergy of antagonists is altered, a vigorous contraction of the weaker muscle may result in injury. Any factor that adversely affects the neuromuscular coordination during running, such as lack of proper

FIGURE 68.1 Tight hamstring muscles may lead to an imbalance between the quadriceps and hamstring muscles, placing an athlete at increased risk for injury.

warm-up, poor training, or muscle fatigue, may result in a strain injury.

Hamstring strains can be divided into three grades according to their severity:

1. Grade I, or first-degree, strain: mild strain with minimal muscle damage (less than 5% of muscle fiber disruption). There is associated pain but little or no loss of muscle strength.
2. Grade II, or second-degree, strain: moderate strain with more severe partial tearing of the muscle but no complete disruption of the myotendinous unit. Pain is present with loss of knee flexion strength.
3. Grade III, or third-degree, strain: severe strain involving complete tearing of the myotendinous unit. This injury presents with severe pain and marked loss of knee flexion strength [1,8].

Avulsion of the hamstrings tendon from its origin on the ischium or distally from the tibia or fibula is not graded like the classic myotendinous strains. These injuries are usually complete or partial avulsion injuries and described as such.

Symptoms

At the time of injury, patients typically report a sudden, sharp pain in the back of the thigh. Some describe a “popping” or tearing sensation. There is generalized pain and point tenderness at the site of injury. The patient may complain of tightness, weakness, and impaired range of motion. Depending on the severity of the injury, the individual may or may not be able to continue the activity and occasionally is unable to bear weight on the affected limb. Swelling and ecchymosis are variable and may be delayed for several days. The ecchymosis may descend to the thigh and be manifested at the distal thigh or back of the knee, calf, or ankle. The injury may occur in the early or late stages of activity, and patients may give a history of inadequate warm-up or fatigue.

Rarely the patient may complain of symptoms of numbness, tingling, and distal extremity weakness. If these are present, further investigation into a sciatic nerve irritation is warranted. Complete tears and proximal hamstring avulsion injuries can cause a large hematoma or scar tissue to form around the sciatic nerve [9,10].

Alternatively, any change in training patterns and increased eccentric exercise in a previously untrained subject can lead to hamstring injury with delayed-onset muscle soreness. This is thought to be the result of microscopic damage followed by a local inflammatory response [11].

Physical Examination

The physical examination begins with assessment of gait abnormalities. Patients with hamstring injuries often have a shortened walking gait or running stride associated with a limp. Swelling and ecchymosis may not be detectable for several days after the initial injury, and the amount of bleeding depends on the severity of the strain. Unlike direct muscle contusions, in which the ecchymosis remains confined to the muscle proper, the bleeding in a hamstring strain can escape through the ruptured fascia with resultant ecchymosis into interfascial spaces, explaining the common finding of ecchymosis distal to the site of injury [12].

The posterior thigh is inspected for visible defects and deformity, asymmetry, swelling, and ecchymosis (Fig. 68.2). The entire length of the hamstrings should be palpated, including the proximal origin near the ischial tuberosity and distal insertions at the posterior knee. A palpable defect in the posterior thigh indicates a more severe injury with possible complete rupture of the muscle.

Active and passive range of motion of the hamstrings should be tested and compared with the contralateral side. Range of motion of the knee can be measured with the hip at 90 degrees in the supine position or sitting position. Deficits in knee and hip range of motion are common, and the point at which pain limits range of motion should be noted (Fig. 68.3). Concentric and eccentric muscle strength testing of the hamstrings should also be performed with the patient both sitting and prone. Weakness of knee flexion and hip extension is common. Asymmetry of the hamstrings can sometimes be accentuated with active-resisted static muscle contraction. A soft tissue defect with distal bulging of the retracted muscle belly indicates a partial or complete rupture.

FIGURE 68.2 Clinical photograph of posterior thigh deformity after complete tear of the hamstrings.

FIGURE 68.3 Measurement of hamstring tightness. With the patient supine and the hip flexed 90 degrees, the knee should extend fully if the hamstrings are flexible. If the knee will not extend completely, the residual knee flexion angle is measured and recorded as hamstring tightness. (From Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

Neurologic examination findings should be normal except for strength testing of the hamstring group and in rare cases when there is an associated sciatic nerve irritation. In these cases, there may be weakness, particularly notable in plantar flexion, and loss of the affected Achilles reflex.

Functional Limitations

Most patients sustaining a hamstring strain have no residual deficits and return to their previous level of function. However, others may experience difficulty with walking or running, time lost from occupation, and delayed return to

sports. Hamstring strains heal slowly and are at high risk for reinjury if return to activities is too early. With severe injuries, it may take up to 1 year for patients to resume preinjury activities; in some cases of complete ruptures, patients never return to the previous level of function [13].

Diagnostic Studies

The common hamstring strain usually requires no additional testing because the diagnosis is made by history and clinical examination. However, more severe cases may warrant diagnostic imaging. If the injury localizes near the origin of the hamstrings, plain radiographs may help identify irregularities of the ischial tuberosity, such as a bone avulsion of the ischial tuberosity (especially in the adolescent). Other radiographic findings may include ectopic calcification consistent with chronic myositis ossificans [4,8]. Magnetic resonance imaging may be used to determine the degree of injury and to identify complete proximal avulsion injuries (Fig. 68.4). Ultrasound imaging, in the hands of an experienced practitioner, may also be used as a diagnostic tool.

Differential Diagnosis

- S1 radiculopathy
- Piriformis syndrome
- Referred pain from sacroiliac joint or lumbar spine
- Bone avulsion or apophysitis of the ischial tuberosity
- Ischial bursitis (weaver's bottom)
- Stress fracture in the pelvis, femoral neck, or femoral shaft
- Adductor magnus strain
- Hip osteoarthritis
- Pelvic floor dysfunction

Treatment

Initial

Initial management of a hamstring strain consists of the PRICE principle (*protection, rest, ice, compression, and elevation*). Relative rest and protection may involve weight bearing as tolerated or, with higher grade injuries (grade II or grade III injuries), cane or crutch walking. Ambulatory aids help prevent tissue irritation and the resulting inflammation, both of which prolong recovery. Assistive devices should be used until the patient can walk without a limp in a normal heel-toe gait. The application of ice as often as every 2 or 3 hours for 20 minutes the first few days is indicated to limit the amount of pain and swelling. Ice provides an anti-inflammatory effect and helps reduce swelling. Icing is continued through the recovery to inhibit inflammation and to allow muscle healing. Compression by taping or elastic wrapping of the thigh combined with elevation reduces hemorrhage, thereby helping control edema and pain. Nonsteroidal anti-inflammatory drugs and other analgesics are commonly used to limit the inflammatory reaction and for pain control in the first few days. Soft tissue mobilization to the site of pain should be avoided for at least 5 days because this may exacerbate the inflammatory response.

FIGURE 68.4 Axial magnetic resonance image demonstrating injury to the semitendinosus (ST), semimembranosus (SM), and biceps femoris (BF) muscles. The sciatic nerve (Sc) is shown anterior to the muscles and within the hematoma of injury.

Rehabilitation

The elements of a hamstring rehabilitation program involve a pain-free progression of stretching, strengthening, and sports-specific activities. In the acute phase, pain-free range of motion should be achieved as soon as possible to prevent adhesions and scarring in the muscle tissue. Patients should start with pain-free active range of motion and progress to pain-free passive range of motion and gentle stretching. For a full stretch of the hamstring muscle to be achieved, the hip must be flexed to 90 degrees and the knee fully extended. This stretch is best achieved in the supine position; a towel can facilitate hamstring lengthening (Fig. 68.5). It is also critical to improve flexibility throughout the spine and lower extremities. Strengthening can begin when the patient achieves full active extension without pain. It is best to start with static contractions, such as multiple-angle submaximal isometric exercises [14]. Once these are performed at

FIGURE 68.5 Stretching the hamstring fully requires the hip to be at 90 degrees with the ankle dorsiflexed. However, forceful stretching should be avoided.

100% effort without pain, the patient may progress to isotonic exercise, such as prone hamstring strengthening and isokinetic exercise. These concentric strength exercises are followed by eccentric strength exercises and sports-specific activities as tolerated. Examples of eccentric training include Nordic hamstring exercises, straight-leg windmills, straight-leg dead lift, and flywheel training [15]. Return to sport is allowed when full motion is restored, strength is at least 90% that of the uninjured side, and hamstring-quadriceps strength ratio is symmetric [6]. Hamstring flexibility must be maintained throughout the rehabilitation process to prevent reinjury. Aerobic conditioning should continue throughout the rehabilitation process. Bicycling *without* toe clips (toe clips increase use of hamstrings), swimming or jogging in a pool, and upper body ergometry are recommended. Rehabilitation programs incorporating progressive agility and trunk stabilization exercising have been shown to decrease reinjury rates [16].

It is critical to educate patients about how to prevent recurrent hamstring injuries. This includes a good warm-up period before engaging in sports. Full return to play must be gradual because the risk of recurrent injury is high. In addition, training errors, such as an abrupt switch to a hard surface or an increase in training intensity, should be avoided.

Procedures

Procedures are not typically performed in hamstring strain injuries. However, the use of platelet-rich plasma to aid in the recovery of high hamstring strains has been gaining popularity [17]. Given the increased use of autologous blood injections and dry needling techniques, further clinical and laboratory research is warranted.

Surgery

Routine hamstring strains do not require surgical intervention and respond well to a conservative rehabilitation program. However, in the case of complete hamstring avulsion from the ischial tuberosity, surgical repair is recommended because of the residual loss of power and function in nonoperatively treated patients [2,3,18]. Surgical neurolysis is also recommended for the rare complication of symptomatic scarring around the sciatic nerve [9,10].

Potential Disease Complications

The most common complication of hamstring strain is recurrent injury. Loss of hamstring flexibility and strength as well as neuromuscular coordination puts the patient at risk for reinjury, especially if the return to activity is before full recovery. The high injury recurrence rate is believed to be due to return to play before full strength is regained in the lengthened hamstring position [19].

Two cases of posterior thigh compartment syndrome have been reported with complete hamstring tears, one resulting from injury alone and one complicated by anticoagulation therapy [20,21]. Complete hamstring tears can also result in substantial scar formation around the sciatic nerve within the posterior thigh. Patients may present with radicular-type symptoms ranging from sensory paresthesias to footdrop.

Patients with chronic complete hamstring avulsion off the ischial tuberosity may complain of pain, weakness, and cramping as well as difficulty in running and walking and poor leg control, especially walking downhill [3].

Potential Treatment Complications

Nonsteroidal anti-inflammatory drugs are known to have gastrointestinal, renal, and liver side effects. Ultrasound therapy should be avoided in the acute treatment of high-degree strains, especially if hematoma formation is suspected, because it may extend the hematoma [21]. Potential complications of surgical repair of an avulsion fracture include sensation loss along the incision site and postoperative sciatica [22].

M24.852 Joint derangement of left hip, not elsewhere classified (snapping hip)
M24.859 Joint derangement of unspecified hip, not elsewhere classified (snapping hip)
M76.30 Iliotibial band syndrome, unspecified leg
M76.31 Iliotibial band syndrome, right leg
M76.32 Iliotibial band syndrome, left leg

Definition

The iliotibial band (ITB) is a dense fascia on the lateral aspect of the knee and hip. Traditionally, the gluteus maximus and tensor fascia lata were thought to be the proximal origin of the ITB. Further anatomic dissections have demonstrated that the gluteus medius also has direct and indirect contributions to the ITB (Fig. 69.1) [1]. Proximal attachment

includes the iliac tubercle or iliac crest [2,3]. In the distal thigh, the ITB attaches to the linea aspera and the upper edge of the lateral femoral epicondyle [3,4]. According to Terry [5], after passing over the lateral femoral epicondyle, it separates into two components. The iliotibial tract of the distal ITB attaches to Gerdy tubercle of the anterolateral proximal tibia. The iliopatellar band of the ITB has aponeurotic connections to the patella and the vastus lateralis [5]. Other distal attachments include the biceps femoris, the lateral patellar retinaculum, and the patellar tendon [5,6]. An anatomic pouch can be found underlying the posterior ITB at the level of the lateral femoral epicondyle [7]. Controversy exists as to whether this pouch is a bursa, a synovial extension of the knee joint, or degenerative tissue [7,8]. Others have reported that a highly innervated fat pad overlies the lateral femoral epicondyle [9].

Iliotibial band syndrome (ITBS) or iliotibial band friction syndrome is an overuse injury typically referring to lateral knee pain as a result of impingement of the distal ITB over the lateral femoral epicondyle. Less commonly, ITBS may refer to hip pain associated with movement of the ITB across the greater trochanter. This chapter deals primarily with distal ITBS. The suspected pain generator in ITBS is as controversial as the anatomy around the lateral epicondyle. It has been postulated to be bursitis, synovitis, or irritation of the fat pad, posterior fibers of the ITB, or periosteum [3,6,9–12]. Although the anatomic pain generator may not be fully known, pain at the distal aspect of the ITB is thought to be caused by the fibers of the ITB passing over the lateral femoral epicondyle with knee flexion and extension [6,11].

Friction has been implicated as the most important factor in ITBS [8,11]. Maximum friction occurs when the posterior fibers of the ITB pass over the lateral femoral epicondyle at 20 to 30 degrees of knee flexion, the putative “impingement zone.” [8] Repeated knee flexion and extension, particularly with increased running mileage per week, creates friction and has been shown to predispose an individual to lateral knee pain [8,11]. Friction has been shown to play a role in cycling activities as well. Cycling-induced ITBS is thought to result

FIGURE 69.1 Anatomy of the iliotibial band, which can cause “snapping” as it slips anteriorly and posteriorly over the prominent greater trochanter.

from the repetitive activity of cycling, as less time is spent in the impingement zone than during running activities [11]. Other authors have theorized that pain is due not only to friction but also to compression of the fat pad between the ITB and the lateral femoral epicondyle. The compression of the fat pad was found to be greatest at 30 degrees of flexion, similar to previous reports, and increased with internal rotation of the tibia during knee flexion [6,9].

Several factors may increase the risk for development of ITBS. Although it has not been extensively studied, poor neuromuscular control appears to be an important *modifiable* risk factor for ITBS. Weakness of hip abductors has been implicated in ITBS [6]. However, difference in strength of hip abduction was not found in a study of 10 runners with ITBS compared with controls [13]. Specifically, neuromuscular control is needed to attenuate the valgus–internal rotation vectors at the knee after heel strike. If appropriate control is not available, the ITB may have an abrupt increase in tension at its insertion site [10,14,15]. Increased hip adduction and knee internal rotation have been noted in

female runners, suggesting increased ITB strain as a mechanism of injury [15]. Increased foot inversion, maximum knee flexion, and knee internal rotation were noted during an exhaustive run in recreational runners with history of ITBS [16]. Peak rearfoot eversion, knee internal rotation angle, and hip adduction angle were increased in 35 female runners with history of ITBS compared with matched controls [17]. Contradictory results were found in a study of 18 runners with ITBS compared with controls. Results indicated decreased hip adduction in those with ITBS, although they were found to have a lack of “coordination” defined as earlier hip flexion and knee flexion [18]. Hamill and colleagues [19] noted that the strain rate of the ITB during stance phase was increased in female runners who developed ITBS compared with healthy age-matched controls, and Miller and coworkers [16] noted increased ITB strain in recreational runners with history of ITBS. Strengthening of the gluteus medius and tensor fascia lata, decelerators of the valgus–internal rotation vectors at the knee, has been shown to reduce symptoms of ITBS [10,20]. Lack of dynamic flexibility, particularly of the ITB, has been implicated with ITB injury susceptibility [6,15,21,22]. No research study to date, though, has revealed a correlation between ITB tightness and ITB injury. Theoretically, however, tightness of the ITB or its constituent muscles increases impingement of the ITB on the lateral femoral epicondyle [8]. Other risk factors that may be attenuated with proper shoe wear or foot orthoses include excessive foot–ankle pronation and supination [6,16]. Training errors, such as rapid changes in training routine, hill training, striding, and excessive mileage, have also been highlighted as increasing the risk of ITBS [6,12]. Increased ground reaction force, as with running in old shoes, may also increase frictional forces at the knee and exacerbate symptoms [8]. Intrinsic or nonmodifiable factors, such as bone malalignment or a wide distal ITB, may contribute to the development of ITBS [22,23]. Finally, repeated direct trauma to the lateral knee, particularly with soccer goalies, appears to be injurious to the ITB impingement area [23].

Symptoms

Symptoms of ITBS occur typically at the lateral femoral epicondyle but may emanate from the distal attachment of the ITB at Gerdy tubercle on the tibia [6,12]. ITBS is the most common cause of lateral knee pain in runners [6]. Individuals present with sharp or burning lateral knee pain that is aggravated during repetitive activity. This pain may radiate up into the lateral thigh or down to Gerdy tubercle [24]. Runners often describe a specific, reproducible time when the symptoms commence [25]. Pain usually subsides after a run; however, in severe cases, persistent pain may cause restriction in distance [26,27]. Runners also note more pain with downhill running because of the increased time spent in the impingement zone [8]. Paradoxically, runners state that faster running and sprinting often do not produce pain. Fast running allows the athlete to spend more time in knee angles greater than 30 degrees [8]. Cyclists present with rhythmic, stabbing pain with pedaling. Specifically, they complain of pain at the end of the downstroke or the beginning of the upstroke. Bikers with improper saddle height and cleat position may experience greater symptoms [28,29].

ITBS symptoms may also occur as a lateral snapping hip. An external or lateral snapping hip occurs as the ITB rapidly passes anteriorly over the greater trochanter as the femur passes from extension to flexion [30]. Athletes, particularly dancers, sometimes experience an audible painful snap on landing in poor turnout (decreased external rotation at the hip) and with excessive anterior pelvic tilt [31].

Physical Examination

Physical examination begins with a screening examination of the joints above and below the site of injury. Hip girdle examination includes an assessment for joint range of motion, asymmetries [32], muscle strength (particularly hip abductors) [10], and lumbopelvic somatic dysfunctions [33]. The modified Thomas and Ober tests are used to assess flexibility of the ITB and related musculature at the hip and knee (Figs. 69.2 and 69.3) [6,12,34].

The knee examination includes palpation, patellar accessory motion [35], and the Noble compression test (Fig. 69.4) [8]. Knee tenderness is noted either at the lateral femoral epicondyle (above the lateral joint line) or at Gerdy tubercle. Palpatory examination should also include a thorough assessment for myofascial restrictions and trigger points along the lateral thigh musculature [25,26]. On rare occasion, ITB swelling and crepitus accompany tenderness. Pain can also be elicited by the Noble compression test [6]. Other conditions are effectively ruled out by performing a relevant physical examination.

The foot and ankle examination is particularly useful in the determination of gastrocnemius-soleus inflexibility, subtalar motion restrictions, and specific foot type (e.g., hindfoot varus). Finally, a biomechanical assessment of sports-specific activity can be done. Walkers and runners are observed for abnormalities such as excessive foot-ankle pronation, inability to attenuate shock at the knee, Trendelenburg frontal plane gait at the pelvis, and forward

trunk lean [33,36]. Bicyclers are observed for proper foot placement on the pedal, saddle height, and knee angles with pedaling revolution [28,29]. Dancers can be observed performing *rond de jambe* or *grand plié* for proper turnout and pelvic stabilization [31].

FIGURE 69.2 Thomas test to assess hip flexion contracture. The patient lies supine while the clinician flexes one of the patient's hips, bringing the knee to the chest to flatten the lumbar spine. The patient holds the flexed knee and hip against the chest. If there is a flexion contracture of the hip, the patient's other leg will rise off the table.

FIGURE 69.3 Ober test to assess contracture of the iliotibial band. The patient is side-lying with the lower leg flexed at the hip and knee. The clinician passively abducts and extends the patient's upper leg with the knee straight (A) or flexed to 90 degrees (B). The test result is positive if the leg remains abducted and does not fall to the table (C).

FIGURE 69.4 Noble compression test to determine whether there is iliotibial band friction at the knee. The patient lies supine, and the knee is flexed to 90 degrees (the hip flexes as well). The clinician applies pressure with the thumb at the lateral femoral epicondyle while the patient slowly extends the knee. The test result is positive if the patient complains of severe pain over the lateral femoral epicondyle at 30 degrees.

The findings of the neurologic examination, including strength, sensation, and reflexes, are typically normal. Strength may be affected by disuse or guarding due to pain, particularly in the hip abductors and external rotators.

Functional Limitations

ITBS pain usually restricts athletes from their sports activity but does not typically cause limitations of daily activities. Yet, a vicious circle is set forth in which biomechanical deficits (e.g., gluteal weakness and ITB tightness) cause ITB tissue injury with resultant functional adaptations to avoid the pain of the tissue injury (e.g., external rotation of the hip) [32].

Diagnostic Studies

Imaging has a limited role in ITBS because it is usually a clinical diagnosis. Radiographs are rarely helpful [12]. Diagnostic ultrasonography has been used in some centers to confirm injuries [37]. Diagnostic ultrasound examination can measure ITB thickness for which normal values have been determined in uninjured subjects [38]. Dynamic sonography may also be helpful in identifying abnormal motion of the proximal ITB in diagnosis of external snapping hip syndrome [39]. When definitive diagnosis is needed or other diagnoses need to be excluded, magnetic resonance imaging has emerged as a potentially useful test. Magnetic resonance imaging may show a thickened ITB or high intensity on axial T2-weighted images [40].

Differential Diagnosis

ILIOTIBIAL BAND: HIP

- Hip joint disease
- Meralgia paresthetica
- Trochanteric bursitis
- Internal snapping hip
- Referred or radicular pain from lumbar spine
- Primary myofascial pain

ILIOTIBIAL BAND: KNEE

- Popliteus tendinitis
- Lateral collateral ligament injury
- Lateral hamstring strain
- Lateral meniscus tear
- Patellofemoral pain
- Common peroneal nerve injury
- Fabella syndrome
- Lateral plica
- Stress fracture
- Primary myofascial pain

Treatment

Initial

Acute phase treatment is akin to that of other musculoskeletal injuries. Relative rest consists of activity modification, particularly with restriction of those activities that exacerbate the pain symptoms [6,26]. In most instances, this does not mean a complete cessation of activity. The clinician needs to emphasize the positive aspects of relative rest and provide alternative training regimens. The ITB can be relatively off-loaded if an individual can keep his or her activity below the threshold of pain. Frequently, this can be achieved by simply decreasing intensity or training duration. Medications such as nonsteroidal anti-inflammatory drugs may help reduce pain and inflammation in the first few weeks of injury. If swelling is present, some authors advocate a local corticosteroid injection in the initial stages [25,26]. As well, modalities such as ice, ice massage, ultrasound, iontophoresis, and phonophoresis can be helpful in the early period to reduce early inflammation and pain [6,11,26]. It is critical early on to address the biomechanical cause of ITB injury [26].

Rehabilitation

Ultrasound, phonophoresis, iontophoresis, and electrical stimulation may also be used to reduce early inflammation and pain [26]. The subacute phase of rehabilitation addresses the biomechanical deficits found on physical examination. Typically, flexibility deficits are seen in the ITB, iliopsoas, quadriceps, and gastrocnemius-soleus [25,26]. Incorporation of flexibility and strengthening into the rehabilitation treatment is often recommended [6,13,26]. Proper stretching addresses all three planes and incorporates proximal and distal musculotendinous fibers.

Fredericson and colleagues [21] studied the relative effectiveness of three commonly prescribed standing ITB stretches. The authors concluded that when overhead arm extension is added to the standing ITB stretch, the ITB

length and average external adduction moments could be increased [21]. This stretch is performed standing with the symptomatic leg extended and adducted across the uninvolved leg. The subject laterally flexes the trunk toward the contralateral side and extends both arms overhead (Fig. 69.5). A study evaluated the effectiveness of the Ober test (see Fig. 69.3) and the modified Ober test in stretching the ITB and the most distal component, the iliotibial tract. The modified test is performed the same as the Ober test except the knee remains extended at 0 degrees. The investigators used ultrasonography to assess the soft tissue changes of the iliotibial tract and concluded that both tests are effective in the initial stages of stretching. However, the modified Ober test may afford a greater stretch of the iliotibial tract of the ITB when additional adduction of the hip is allowed [41]. In a cadaveric study, Falvey and colleagues [3] found limited ability to lengthen the ITB by the modified Ober test and by hip flexion, adduction, and external rotation with knee flexion (hip test) compared with control (straight-leg raise), although the hip test had significantly greater strain. In another limb of the same study, they found minimal change in length with isometric contraction of the tensor fascia lata, concluding that focus should be on stretching the muscle component of the ITB complex. Some muscle groups do not respond to stretch unless myofascial and joint restrictions are concomitantly addressed by experienced therapists or by self-administered techniques [25,26]. In a systematic review by Ellis and coworkers [11], one study of transverse friction massage was not found to be beneficial. Proper facilitation of hip girdle musculature can be achieved by addressing antagonistic tight structures, such as tight hip flexors or anterior hip capsule [34]. Subtalar mobilizations are often needed to prevent excessive valgus–internal rotation forces from transferring to the knee and ITB [36]. In

conjunction with a flexibility and joint mobilization program, strengthening of weak or inhibited muscles can be started. Strengthening regimens ultimately need to move away from the plinth to more functional activities, such as single squats and lunges, with an emphasis on proper pelvic and core stabilization [26,33].

Finally, the maintenance phase focuses on returning patients to their respective activities with confidence in their functional abilities. In this phase, athletes are ideally observed or videotaped in their sporting environment. Frequently, runners have form deviations that lead to uncontrolled valgus–internal rotation of the knee. These abnormalities include excessive pronation, inability to shock attenuate at the knee, and Trendelenburg frontal plane gait at the pelvis [33,36]. A change to shock-absorbing or motion-control shoes can accommodate supination and overpronation, respectively [36]. Foot orthoses have also been advocated for runners with lower limb injuries. Their benefit is as yet empirical. Cyclists can often correct their ITB problems with equipment and bicycle adjustments [24,28]. Dancers performing *rond de jambe* or *grand pli  * can be cued on maintaining turnout and neutral pelvic position [34]. After sports-specific adjustments have been made, athletes need to be reintroduced to activity gradually and individually.

Procedures

Corticosteroid injections may be performed at different locations along the ITB. Injection into the anatomic pouch at the lateral femoral epicondyle is a relatively simple procedure and is advocated for patients with persistent pain and swelling (Fig. 69.6) [25]. A mixture of anesthetic (e.g., 1 mL of 1% lidocaine) and long-acting steroid (e.g., 1 mL of betamethasone) is instilled to the affected site. A randomized controlled study evaluating the efficacy of corticosteroid injections in runners with acute symptoms of ITB-mediated pain showed that runners in the injection group experienced less pain during running activities [42]. Steroid injections should be repeated only if adequate relief is obtained after the initial injection. Patients can return to play as their pain allows.

FIGURE 69.5 Iliotibial band (ITB) stretch.

FIGURE 69.6 Distal iliotibial band injection technique at the lateral epicondyle of the femur.

Surgery

Surgical treatment of ITBS is rarely needed. Surgery involves excision of the posterior half of the ITB where it passes over the lateral femoral epicondyle, Z lengthening, or removal of the underlying putative bursa by open or endoscopic techniques [12,43,44]. These procedures appear to have mixed results and should be contemplated only for patients who have exhausted all other options, including a comprehensive rehabilitation program as previously outlined.

Potential Disease Complications

If ITBS is not properly addressed, biomechanical adaptations can occur [32]. Chronic pain, leading to progressive disability, is a potential complication.

Potential Treatment Complications

Rehabilitation complications are rare. Nonsteroidal anti-inflammatory drugs and analgesics have well-known side effects that may affect gastrointestinal, hepatic, or renal function. Corticosteroid injections have the potential complications of infection, depigmentation of skin, and flare of symptoms at the site of injection. Surgical procedures for ITBS carry inherent risks. Postoperative infection and other standard risks should be explained to patients before surgical interventions. Overall, interventional procedures for the ITB carry few risks or complications.

 M17.5 Other unilateral secondary osteoarthritis of knee
 M12.561 Traumatic arthropathy, right knee
 M12.562 Traumatic arthropathy, left knee
 M12.569 Traumatic arthropathy, unspecified knee

Definition

Osteoarthritis is steadily becoming the most common cause of disability for the middle-aged and has become the most common cause of disability for those older than

65 years [1]. The knee joint is the most common site for lower extremity osteoarthritis [2]. It is estimated that nearly half of all adults will have symptomatic knee osteoarthritis in their lifetimes [3]. In addition to the growing population of elderly patients with knee osteoarthritis, an increasing number of former athletes with previous knee injuries may experience post-traumatic knee osteoarthritis. Osteoarthritis of the knee results from mechanical and idiopathic factors. Osteoarthritis alters the balance between degradation and synthesis of articular cartilage and subchondral bone.

Osteoarthritis can involve any or all of the three major knee compartments: medial, patellofemoral, or lateral. The medial compartment is most often involved, leading to medial joint space collapse and thus to a genu varum (bowleg) deformity. Lateral compartment involvement may lead to a genu valgum (knock-knee) deformity. Isolated disease of the patellofemoral joint occurs in up to a quarter of patients with osteoarthritis of the knee [4]. Arthritis in one compartment may, through altered biomechanical stress patterns, eventually lead to involvement of another compartment.

Osteoarthritis affects all structures within and around a joint. Hyaline articular cartilage is lost. Bone remodeling occurs, with capsular stretching and weakness of periarticular muscles. Synovitis is present in some cases and ligamentous laxity occurs. Lesions in the bone marrow may also develop, which may suggest trauma to bone [5]. Osteoarthritis involves the joint in a nonuniform and focal manner. Localized areas of loss of cartilage can increase focal stress across the joint, leading to further cartilage loss. With a large enough area of cartilage loss or with bone remodeling, the joint becomes tilted, and malalignment develops.

The threat of knee osteoarthritis is not only a concern for elderly populations. Malalignment is the most potent risk factor for structural deterioration of the knee joint [6]. By further increasing the degree of focal loading, malalignment creates a vicious circle of joint damage that ultimately can lead to joint failure. The role of obesity as a risk factor for knee osteoarthritis has been well documented. A large, population-based prospective study found that the risk for knee osteoarthritis was seven times greater for people with a body mass index of 30 or higher compared with those with a body mass index below 25 [7]. Moreover, women (of average height) who lost 5 kg of weight reduced their risk of symptomatic knee osteoarthritis by 50% [8].

Sports injuries and vigorous physical activity are considered to be important risk factors in knee osteoarthritis. Elite athletes who take part in high-impact sports, such as soccer and ice hockey, have an increased risk of knee osteoarthritis [9]. It is unclear whether the increased risk in this particular study was directly related to traumatic injury. However, it has been suggested in another study that subjects with a history of knee injury are at a five-fold to sixfold increased risk for development of knee osteoarthritis [10]. Knee osteoarthritis is common in those performing heavy physical work, especially if this involves knee bending, squatting, kneeling, or repetitive use of joints [11]. It is unclear if the association of knee osteoarthritis with these work-related activities is secondary to the nature of the work or the increased likelihood of injury.

Symptoms

Knee osteoarthritis is characterized by joint pain, tenderness, decreased range of motion, crepitus, occasional effusion, and often inflammation of varying degrees. Initial osteoarthritis symptoms are generally minimal, given the gradual and insidious onset of the condition. Pain typically occurs around the knee, particularly during weight bearing, and decreases with rest. With progression of the disease, pain can persist even at rest. Activities associated with osteoarthritic pain are climbing stairs, getting out of a chair, getting in and out of a car, and walking long distances. Pain may also radiate to adjacent sites as osteoarthritis indirectly alters the biomechanics of other anatomic structures, such as ligaments, muscles, nerves, and veins.

Joint stiffness may occur after periods of inactivity, such as after awakening in the morning or prolonged sitting. Patients often report higher pain levels in the morning but usually for less than 30 minutes. Patients often experience limitation of movement because of joint stiffness or swelling. Many patients report a “locking” or a “catching” sensation, which is probably due to a variety of causes, including debris from degenerated cartilage or meniscus in the joint, increased adhesiveness of the relatively rough articular surfaces, muscle weakness, and even tissue inflammation. Stiffness can discourage mobility. This initiates a cycle that results in deconditioning, decreased function, and increased pain.

Barometric changes, such as those associated with damp, rainy weather, will often increase pain intensity. Patients often note that their knees “give way” or feel unstable at times.

Physical Examination

Examination of the patient includes testing for various possible causes of knee pain (see section on differential diagnosis). Therefore the entire limb, from the hip to the ankle, is examined. It is important to identify findings such as quadriceps weakness or atrophy and knee and hip flexion contractures. Gait should be observed for presence of a limp, functional limb length discrepancy, or buckling. Genu varum or valgum is often better appreciated when the patient is standing.

Table 70.1 Typical Physical Examination Findings in Knee Osteoarthritis

Inspection	Bone hypertrophy Varus deformity from preferential medial compartment involvement
Palpation	Increased warmth Joint effusion Joint line tenderness
Range of motion	Painful knee flexion Decreased joint flexion secondary to pain
Joint stability	Crepitus (coarse) Mediolateral instability

The affected knee should be compared with the contralateral uninvolved knee. Knee examination may reveal decreased knee extension or flexion secondary to effusion or osteophytes (both of which may be palpable). Osteophytes along the femoral condyles may be palpated, especially along the medial distal femur. Palpation may reveal patellar or parapatellar tenderness. Crepitation, resulting from juxtaposition of roughened cartilage surfaces, may be appreciated along the joint line when the knee is flexed or extended. A mild effusion and tenderness may be appreciated along the medial joint line or at the pes anserine bursa. Ligament testing may reveal laxity of one or both of the collateral ligaments. Lateral subluxation of the patella may be found in patients with genu valgum (Table 70.1). Another clue on examination that the patient probably has knee osteoarthritis is the finding of visible bone enlargements (exostoses) of the fingers. At the distal interphalangeal joints, these are referred to as Heberden nodes; at the proximal interphalangeal joints, they are known as Bouchard nodes, usually a slightly later finding.

The findings of the neurologic examination are typically normal, with the exception of decreased muscle strength, particularly in the quadriceps, due to disuse or guarding secondary to pain.

Diagnostic Studies

Osteoarthritis is diagnosed clinically on the basis of history and physical examination. Imaging, however, can be used to confirm the diagnosis and to rule out other conditions. Radiographic abnormalities can be found both in joint areas subjected to excessive pressure and in joint areas subjected to diminished pressure. These changes include joint space narrowing, subchondral sclerosis, and bone cysts in weight-bearing regions of the joint and osteophytes in low-pressure areas, especially along the marginal regions of the joint. Joint space narrowing is the initial finding, followed by subchondral sclerosis, then by osteophytes, and finally by cysts with sclerotic margins (known as synovial cysts, subchondral cysts, subarticular pseudocysts, or necrotic pseudocysts).

Radiographic evidence of osteoarthritis is not well correlated with symptoms [12]. Results have been conflicting, probably because of the differences in populations studied and radiographic and clinical criteria used. The presence of osteophytes had a strong association with knee pain, whereas the absence or presence of joint space narrowing was not associated with pain [13].

Knee pain severity was a more important determinant of functional impairment than radiographic severity of osteoarthritis [14,15]. There was no correlation between joint space narrowing and a disability score (Western Ontario and McMaster Universities Osteoarthritis index, WOMAC) at a single time point [15].

Osteophytes *alone* are associated with aging rather than with osteoarthritis. Indications for plain x-ray films include trauma, effusion, symptoms not readily explainable by physical examination findings, severe pain, presurgical planning, and failure of conservative management. Recommended films are weight-bearing (standing) anteroposterior, lateral, and patellar views. Radiographs taken during weight bearing with the knee in full extension and partial flexion may reveal a constellation of findings associated with osteoarthritis, including asymmetric narrowing of the joint space (typically medial compartment), osteophytes, sclerosis, and subchondral cysts (Fig. 70.1). A Merchant view specifically evaluates the patellofemoral space. Non-weight-bearing lateral views may help in the evaluation of the patellofemoral and tibiofemoral joint spaces. Tunnel views can help visualize loose osteochondral bodies.

Magnetic resonance imaging usually adds little but cost to the entire evaluation of osteoarthritis of the knee. It may reveal changes that suggest the presence of osteoarthritis. However, it is not indicated in the initial evaluation of older persons with chronic knee pain. Magnetic resonance imaging may detect incidental findings, such as meniscal tears, that are common in middle-aged and older adults with and without knee pain. Musculoskeletal ultrasonography has potential for detecting bone erosions, synovitis, tendon disease, and enthesopathy. It has a number of distinct advantages over magnetic resonance imaging, including good patient tolerability and ability to scan multiple joints in a short time. However, there are scarce data about its validity, reproducibility, and responsiveness to change, making interpretation and comparison of studies difficult. In particular, there are limited data describing standardized scanning methodology and standardized definitions of ultrasound pathologic changes [16].

Laboratory test results are typically normal, but analysis may be undertaken, especially for elderly patients, to establish a baseline (e.g., blood urea nitrogen concentration, creatinine concentration, or liver function tests before use of nonsteroidal anti-inflammatory drugs or acetaminophen) or to exclude other conditions such as rheumatoid arthritis. Synovial fluid analysis should not be undertaken unless destructive, crystalline, or septic arthritis is suspected.

Differential Diagnosis

COMMON CAUSES OF KNEE PAIN BY AGE GROUP

Children and adolescents	Patellar subluxation Osgood-Schlatter disease Patellar tendinitis Referred pain (e.g., slipped capital femoral epiphysis) Osteochondritis dissecans Subchondral fracture Genetic or congenital defect Septic arthritis Tumor
--------------------------	--

FIGURE 70.1 Knee radiograph demonstrating osteophytes (arrows) and medial joint space narrowing consistent with degenerative arthritis. (From West SG. *Rheumatology Secrets*. Philadelphia, Hanley & Belfus, 1997.)

Adults	Patellofemoral pain syndrome (chondromalacia patellae) Medial plica syndrome Pes anserine bursitis Trauma: ligamentous sprains Meniscal tear Inflammatory arthropathy: rheumatoid arthritis, Reiter syndrome Septic arthritis Lumbar radiculopathy Tumor
Older adults	Osteoarthritis Crystal-induced inflammatory arthropathy: gout, pseudogout Rheumatoid arthritis Popliteal cyst Tumor

DIFFERENTIAL DIAGNOSIS OF KNEE PAIN BY ANATOMIC SITE

Anterior knee pain	Patellar subluxation or dislocation Tibial apophysitis (Osgood-Schlatter lesion) Jumper's knee (patellar tendinitis) Patellofemoral pain syndrome (chondromalacia patellae)
Medial knee pain	Medial collateral ligament sprain Medial meniscal tear Pes anserine bursitis Medial plica syndrome
Lateral knee pain	Lateral collateral ligament sprain Lateral meniscal tear Iliotibial band tendinitis
Posterior knee pain	Popliteal cyst (Baker cyst) Posterior cruciate ligament injury

Treatment

Initial

The PRICE regimen may help provide initial relief for patients in pain: *pro*tection with limited weight bearing by use of a cane or modification of exercise to reduce stress; relative

Table 70.2 Pharmacologic and Supplemental Nutrition Treatment Options

Medication	Related Details
Acetaminophen Oral NSAIDs	The maximum dosage is 4 g/day in patients with normal hepatic function. Studies show almost equal efficacy among traditional NSAIDs [18]. A randomized prospective study demonstrated equal efficacy between selective cyclooxygenase 2 inhibitors and traditional NSAIDs [19].
Tramadol-acetaminophen	American Pain Society guidelines recommend tramadol-acetaminophen for treatment of osteoarthritis pain when NSAIDs alone cannot provide adequate relief. It is considered safe and effective in a subset of elderly patients [20].
Oxycodone	Patients with moderate to severe pain from osteoarthritis can achieve effective pain relief without deterioration in function when opioids are included as part of a comprehensive pain management program [21].
Topical NSAIDs	A quantitative systematic review of 86 trials evaluating the efficacy of topical NSAIDs in osteoarthritis and tendinitis found them significantly more effective than placebo [22].
Topical capsaicin Glucosamine sulfate (1500 mg orally qd) and chondroitin sulfate (1200 mg orally qd)	Limited data from controlled trials have shown improvements with capsaicin [23]. One large randomized clinical trial found that glucosamine and chondroitin sulfate alone or in combination did not reduce pain effectively in the overall group of patients with osteoarthritis of the knee. However, the combination of glucosamine and chondroitin sulfate was effective in the subgroup of patients with moderate to severe knee pain [24].

NSAIDs, nonsteroidal anti-inflammatory drugs.

rest (or taking adequate rests throughout the day, avoiding prolonged standing, climbing of stairs, kneeling, deep knee bending); ice (applied while the skin is protected with a towel for up to 15 minutes at a time several times a day; note, however, that some patients with chronic pain may find better relief with moist heat); compression (if swelling exists, wrapping with an elastic bandage or a sleeve may help); and elevation (may help diminish swelling, if it is present). There are a wide variety of initial treatment options for knee arthritis. Current guidelines put forth by the American College of Rheumatology emphasize the use of acetaminophen as a first-line therapy for osteoarthritis [17]. Other options include oral and topical nonsteroidal anti-inflammatory drugs; topical capsaicin cream; and nutritional intervention, such as glucosamine sulfate and chondroitin sulfate (Table 70.2). Orthotics and footwear are also included in the list of treatment options and are discussed further in the next section.

Rehabilitation

Exercise

Exercises are likely to be most effective if they train muscles for the activities a person performs daily [25]. Randomized studies support the benefits of exercise, even if it is home based, on pain and function in patients with osteoarthritis [26]. Because there is currently no cure for osteoarthritis, most research continues to evaluate the use of exercise as a treatment to alleviate symptoms of the disease and to enhance functional capacity. Two meta-analyses published in 2004 focus specifically on the efficacy of strengthening [27] and aerobic exercise [28] for osteoarthritis.

With regard to muscle strengthening, improvements in strength, pain, function, and quality of life were noted. However, there was no evidence that the type of strengthening exercise influences outcome. Static or dynamic strengthening exercises can maintain or improve periarthicular muscle strength, thereby reversing or preventing

biomechanical abnormalities and their contribution to joint dysfunction and degeneration.

With regard to aerobic exercise, results indicated that aerobic exercise alleviates pain and joint tenderness and promotes functional status and respiratory capacity. Aerobic exercise improves activity tolerance, increases pain threshold, and can have positive effects on mood and motivation for participation in other activities. Whereas strengthening appears superior to aerobic exercise in the short term for specific impairment-related outcomes (e.g., pain), aerobic exercise appears more effective for functional outcomes in the longer term. There is also evidence that exercise can improve proprioception [27], thus improving biomechanics and protective responses.

Attempts to maintain function can be helped through non-weight-bearing strengthening, especially of the quadriceps. For patients with greater pain, this can be done with static exercise or through water aerobics, which allows motion at the knee with reduced joint loads. Exercise bicycles and walking should be recommended to enhance aerobic capacity. Deep knee bends in the presence of effusion should be avoided. Particular attention must be paid to strengthening of the medial quadriceps in patients with genu valgum who have lateral subluxation of the patella. Maintaining activity is critical to maintaining function. Even those patients scheduled for total knee arthroplasty should pursue static and dynamic strengthening as well as cardiovascular conditioning preoperatively to ease the postoperative rehabilitation [29].

Therapeutic Modalities

Transcutaneous electrical nerve stimulation (TENS), the application of an electrical current through the skin with the aim of pain modulation, is a frequently used modality in knee osteoarthritis. Although this is a popular treatment option, research supporting its efficacy is lacking. The treatment is supported only by a few small, short-term trials. In a small-scale, randomized, double-blind crossover trial comparing active and placebo TENS for symptomatic knee

osteoarthritis in subjects who were considered to be candidates for total knee replacement, patients reported significantly more pain relief and less medication use with active TENS therapy than with the placebo [30]. For most patients, pain relief was experienced only during periods of active use of the device, although the beneficial effect was sustained for several hours in a few. Despite the positive results in these small trials, a meta-analysis could not confirm this modality's effectiveness. The systematic review attributed inconclusive results to questionable methodologic quality and a high degree of heterogeneity among trials [31].

Additional therapeutic modalities, such as electrical stimulation or massage, may also be used. Therapists may also review postural alignment and joint positioning techniques, especially for when the patient is sleeping. In particular, the use of a pillow under bent knees, much favored by many patients when they are supine, should be avoided because resulting knee flexion contractures, even if small, can significantly increase stresses on the knee during gait. Stretching of the hamstrings and quadriceps may also prove beneficial. Patients should be counseled against prolonged wearing of high heels, which is associated with medial knee osteoarthritis [32].

Adaptive Equipment

Adaptive equipment, such as a cane or walker, can reduce hip or knee loading, thereby reducing pain. It may also prevent falls in patients with impaired balance. Proper training in the use of a cane is important because it reduces joint loading in the contralateral hip but amplifies forces in the ipsilateral hip.

Bracing and Footwear

The basic rationale for a knee brace for unicompartmental knee osteoarthritis is to improve function by reducing the patient's symptoms. This can be accomplished, in theory, by reducing the biomechanical load on the affected compartment of the knee. Clinical trials are generally small and difficult to control adequately because of the nature of knee braces and the difficulty in designing a trial with a true placebo. Also, each brace has a unique design and may have features that make it more or less acceptable to the patient. Therefore clinical trials done with one brace design may not be applicable to all osteoarthritis knee braces.

A review of the published literature on knee bracing for osteoarthritis points out some of the limitations of the clinical trials to date but acknowledges the limited evidence for improvement in pain and function in patients using osteoarthritis braces compared with medical treatment or neoprene sleeves [33].

In patients with osteoarthritis and varus malalignment of the knees, a shoe wedge (thicker laterally) moves the center of loading laterally during walking, a change that extends from foot to knee, lessening medial load across the knee. Although such modifications to footwear decrease varus malalignment [34], one randomized trial [35] showed no reduction in pain compared with a neutral insert. However, a review of the published literature on the efficacy of laterally wedged foot orthotics for improving these symptoms does indicate a strong scientific basis for applying wedged insoles in an attempt to reduce pain in patients with medial compartment knee osteoarthritis [36].

Tilting or malalignment of the patella may cause patellofemoral pain. Patellar realignment with the use of braces or tape to pull the patella back into the trochlear sulcus of the femur or to reduce its tilt may lessen pain. In clinical trials with tape to reposition the patella into the sulcus without tilt, knee pain was reduced compared with placebo [37,38]. However, patients may find it difficult to apply tape, and skin irritation is common. Commercial patellar braces are also available, but their efficacy has not been studied formally.

Heel lifts or built-up shoes may be required in the presence of leg length discrepancy to prevent compensatory knee flexion gait on the longer side. In the presence of knee deformity, therapists can also evaluate for altered biomechanics (e.g., genu varum may lead to femoral internal torsion, resulting in compensatory external rotation of the tibia, which predisposes the patient to increased arthritic changes). Therapists can also visit the homes and workplaces of patients to suggest adjustments, such as raised toilet seats, grab bars, reachers, and the like.

Acupuncture

Acupuncture, a technique in existence for thousands of years, has gained renewed interest as a treatment of osteoarthritis. A multicenter, 26-week National Institutes of Health-funded randomized controlled trial found acupuncture to be effective as adjunctive therapy for reducing pain and improving function in patients with knee osteoarthritis [39].

Procedures

Intra-articular corticosteroid injections may help in reduction of local inflammation and improvement of symptoms. The response is generally rapid but may not be sustained in the longer term. A systematic review of intra-articular corticosteroid injections demonstrated evidence of pain reduction at 2 weeks and at 3 weeks after intervention. At 4 to 24 weeks after injection, evidence of an effect on pain and function was lacking [40]. Because the corticosteroid is delivered directly, systemic toxicity is minimized. Intra-articular corticosteroid injections should be given no more than two or three times a year to reduce potential damage to cartilage from the steroids. Given the short-term effect and limitation on injection frequency, corticosteroid injection is most often used as an adjunctive therapy for acute or severe symptom flares (Fig. 70.2). Table 70.3 lists potential systemic side effects of corticosteroid injections. Administration of steroids through iontophoresis may be an alternative for patients hesitant to undergo injections.

The authors' preferred technique for intra-articular injection of the knee is as follows. With the patient supine, under sterile conditions with use of a 25-gauge needle, 2 or 3 mL of local anesthetic (e.g., 1% lidocaine) is injected just posterior to the upper lateral pole of the patella. Alternatively, ethyl chloride spray can be used. Then, by use of a 1½-inch, 22- to 25-gauge needle, either local steroid (e.g., methylprednisolone, 20 to 40 mg/mL) or hyaluronic acid is injected in the same region (these products are available in 2-mL vials or prefilled syringes, one injection per vial). If a knee effusion exists, it may be necessary to drain the effusion to avoid dilution of the medications. This is ideally done with an 18- to 20-gauge needle. Switching of

FIGURE 70.2 Location for needle insertion.

Table 70.3 Minimizing Potential Side Effects of Intra-articular Corticosteroid Injection

Side Effect	Ways to Minimize Risk
Systemic effects	Avoid high doses and multiple simultaneous injections; use accurate injection techniques
Tendon rupture, fat atrophy, muscle wasting, skin pigment changes	Avoid misdirected injections
Septic arthritis	Use sterile technique; withhold therapy in at-risk patients
Nerve and blood vessel damage	Use accurate injection techniques
Postinjection symptom flare or synovitis	Avoid the same preparation for future injections
Flushing	Avoid high doses
Anaphylaxis	Take careful drug allergy history
Steroid arthropathy	Avoid high doses and overly frequent injections

the syringes while the needle remains in place prevents additional trauma. Postinjection care includes local icing for 5 to 10 minutes. Patients are advised to avoid excessive weight bearing for 24 to 48 hours after an injection.

Viscosupplementation with hyaluronic acid, available as naturally occurring hyaluronan or synthetic hylan G-F 20, may be helpful. The rationale for using viscosupplementation is to impart protective properties to synovial fluid, including shock absorption, energy dissipation, and lubrication of the articular cartilage surface [41]. Hyaluronan is administered in a series of five weekly injections; hylan G-F 20 is given in three weekly injections. Treatments are typically repeated two to four times per year. Clinical trials of viscosupplementation have demonstrated limited efficacy in pain relief [42]. Compared with corticosteroid injection, the effect of hyaluronic acid appears to be less dramatic but more durable. In a meta-analysis comparing both interventions, hyaluronic acid was less effective for pain relief in the first 4 weeks after injection [43]. By week 4, the two approaches had equal efficacy. Beyond week 8, hyaluronic acid had a greater effect [43]. Side effects included local inflammation and increased pain at the injection site. There is no evidence that hyaluronan injection in humans alters biologic processes or progression of cartilage damage. The hyaluronic acid is injected into the knee in the same manner as the intra-articular steroid is administered.

Surgery (Table 70.4)

Most would agree that the term *arthroscopic débridement* includes lavage and the removal of loose bodies, debris, mobile fragments of articular cartilage, unstable torn menisci, and impinging osteophytes. However, it is clear from the literature that drilling, abrasion chondroplasty, microfracture, saucerization, notchplasty, osteophyte removal, synovectomy, and arthrolysis are also performed simultaneously in many clinical series. Patients who have a short history and a sudden onset of mechanical symptoms and also have knee effusions are likely to do best [44]. Meniscal symptoms and signs, synovitis or synovial impingement, osteophytic impingement, and catching or locking caused by loose bodies favor a good

Table 70.4 Surgical Options for Osteoarthritis of the Knee

Established Techniques	Indications	Outcome
Arthroscopic débridement	Knee effusions Meniscal signs and symptoms Synovitis Osteophytic impingement Catching or locking caused by loose bodies	Most reports show improvement in 50% to 80% of patients; however, results deteriorate with time
Osteotomy of the proximal tibia or distal femur	Predominantly medial compartment involvement	Recovery is prolonged Relief of symptoms often incomplete
Unicompartmental knee replacement	Predominantly medial compartment involvement Minimal lateral compartment disease No major anterior knee pain Stable knee joint Correctable varus deformity Fixed flexion deformity of less than 10 degrees	Survivorship rate for implants of 90% at 20 years
Patellofemoral replacement	Isolated patellofemoral joint involvement	Results have been variable
Total knee replacement	Tricompartmental disease	Survival rates of between 84% and 98% at 15 years

outcome. Significant instability and malalignment are poor prognostic factors. Patients who have radiographic signs of advanced degeneration are unlikely to benefit [45].

Although arthroscopic surgery has been widely used for osteoarthritis of the knee, scientific evidence to support its efficacy is lacking. Most of the orthopedic literature supporting its use is based on retrospective studies, with authors reporting improvement in 50% to 80% of patients [46,47]. However, in a randomized, controlled trial, arthroscopic surgery for osteoarthritis of the knee provided no additional benefit to optimized physical and medical therapies [48].

Up to a quarter of patients with osteoarthritis of the knee have predominantly arthritis of the medial compartment. The surgical options for such patients are medial unicompartmental knee replacement, proximal tibial or distal femoral osteotomy, and total knee replacement (see Chapter 80). Osteotomy is a less drastic measure than knee replacement and is often favored by younger, active patients with unicompartmental symptoms. In osteotomy, a wedge-shaped piece of bone is removed from either the femur or tibia to bring the knee joint back into a more physiologic alignment. This procedure moves the weight-bearing axis to the less damaged compartment. Recovery is prolonged and relief of symptoms often incomplete, but osteotomy may delay the need for total knee replacement for 5 to 10 years [49,50]. Successful treatment could allow a return to sport. The risks specific to this surgery depend on the technique and include nonunion at the osteotomy site, common peroneal nerve injury, pain from the proximal tibiofibular joint, and overcorrection or undercorrection of the deformity. Part of an ongoing debate within the orthopedic community concerns the relative merits of high tibial osteotomy compared with unicompartmental knee replacement in younger patients. Unicompartmental knee replacement requires a smaller surgical approach than for total knee replacement, leading to less blood loss and quicker rehabilitation. The range of knee motion after unicompartmental knee replacement is generally superior to that after total knee replacement. Finally, revision of a unicompartmental knee replacement to a total knee replacement is potentially more straightforward than revision of a total knee replacement [51]. The prerequisites for a unicompartmental knee replacement include stability of the joint, correctable varus deformity, fixed flexion deformity of less than 10 degrees, and minimal lateral compartment disease. Radiographic evidence of patellofemoral osteoarthritis is not necessarily a problem, provided patients do not have major anterior knee pain. Survivorship rates for implants are estimated at 93% and 90% at 15 and 20 years, respectively [52]. These rates are comparable to the best reported for total knee replacement and are an improvement on rates previously reported for unicompartmental knee replacement.

The relative merits of unicompartmental knee replacement over total knee replacement or proximal tibial osteotomy in young (<60 years) active patients continue to be debated. Unicompartmental knee replacement has now become an accepted treatment for older patients with medial compartment arthritis. The results of unicompartmental knee replacement in lateral compartment disease have yet to be fully determined. Total knee replacements, with a quarter-century track record, have generally provided most patients with good pain relief. Whereas joint replacement surgery has been found in numerous studies to provide pain

relief, it paradoxically may lead to increase of services as patients become more mobile [53].

Patients considered for patellofemoral replacement must be assessed for degenerative changes in the rest of the knee joint. Several types of patellofemoral arthroplasties are available, but the results have been variable, highlighting the need for careful selection of patients [54–56]. The most common problems are maltracking of the patella, excessive wear of the polyethylene implant, and disease progression in the rest of the knee joint. Severe chondromalacia may necessitate patellectomy (patella excision). Knee arthrodesis today is generally reserved for patients in whom knee replacement surgery fails. Other less commonly used surgical options, such as synovectomy and small prostheses (to correct deformity), are also possible.

Potential Disease Complications

Progressive knee osteoarthritis may result in reduced mobility and the general systemic complications of immobility and deconditioning. Antalgic gait can result in contralateral hip disease (e.g., greater trochanteric bursitis). The risk of falls will be increased by decreased mobility at the knee. Complaints of chronic pain may result from the initial knee osteoarthritis if it is inadequately treated.

Potential Treatment Complications

Complications of anti-inflammatory medication and steroid injections are well known. Repeated steroid injections can lead to further cartilage destruction as well as to sepsis. Infection is a rare but possible result of joint injection or surgery. Cryotherapy or heat therapy can, of course, lead to frostbite or burns. Hyaluronic acid injections may result in localized transient pain or effusion.

Arthroscopy may damage the articular surface membrane, thus initiating damage to uninvolved cartilage. Excessive arthroscopic scraping has sometimes been associated with persistent pain. The possibility of infection and deep venous thrombosis and the small but real possibility of intraoperative mortality limit the use of surgery to a last-line option. One series of patients *not* taking anticoagulants experienced a 50% rate of deep venous thrombosis, 14.5% of which was proximal deep venous thrombosis [57], thus indicating the importance of anticoagulation, which reduces the risk to less than 5%. In any case, mechanical wear and prosthesis loosening, especially for cemented prostheses, often lead to the need for revision after a decade or so.

 M70.52 Other bursitis of knee, left knee

Definition

Knee bursitis is an inflammation of any bursa in the region of the knee joint and is a common clinical disorder that may lead to functional difficulties. Eleven bursae are found within this region (Fig. 71.1) [1]. Three bursae communicate with the knee joint: quadriceps or suprapatellar, popliteus, and medial gastrocnemius. Four bursae are associated with the patella: superficial and deep prepatellar, and superficial and deep infrapatellar. Two are related to the semimembranosus tendons, and two are related to the collateral ligaments of the knee (one of which is under the pes anserinus, or the conjoined tendons of the sartorius, gracilis, and semitendinosus muscles) [1].

In the popliteal fossa, a bursa is located between the medial head of the gastrocnemius and semimembranosus tendon. Swelling in this area is also called Baker cyst and may actually be due to other inflammatory or degenerative conditions (see Chapter 64). For this chapter's purpose, discussion is limited to knee bursitis arising from inflammation of the previously mentioned bursae.

The most common knee bursitis conditions are the following.

Prepatellar bursitis (housemaid's knee) is caused by direct trauma, such as falling on a bent knee or frequent kneeling on a hard surface [1]. A case of a massive prepatellar bursitis from chronic crawling as a means of household ambulation in an adult man with cerebral palsy has been reported [2]. In 376 subjects with knee pain and radiographic evidence of knee osteoarthritis, 3.1% had evidence of prepatellar bursitis on magnetic resonance imaging [3].

Infrapatellar bursitis (vicar's knee) is usually due to repetitive knee flexion in weight bearing, such as deep knee bends, squatting, or jumping; it can be associated with patellar-quadriceps tendinitis [4,5]. In 376 subjects undergoing routine magnetic resonance imaging who had

FIGURE 71.1 Bursae around knee joint.

knee pain and radiographic evidence of knee osteoarthritis, 10.6% had evidence of superficial infrapatellar bursitis [3].

Anserine bursitis is commonly seen in overweight older women who also have osteoarthritis of the knees and in individuals who participate in sports that require running, side-to-side movement, and cutting [5,6]. In a study involving persons with a symptomatic knee presenting to an orthopedic clinic with suspected internal knee derangement who had magnetic resonance imaging, only 2.5% of these patients had radiologic evidence of pes anserine bursitis, with no gender preference [7].

Medial collateral ligament bursitis refers to inflammation of a bursa located between the deep and superficial parts of the medial collateral ligament [5]. It has been associated with degenerative disease of the medial joint compartment, with marginal osteophytic spur formation [8]. Furthermore, this bursitis may be seen in equestrian and motorcycle athletes because of the friction applied to the medial side of the knee [8].

Semimembranosus bursitis is usually seen in runners and may be associated with hamstring tendinitis [4]. This was seen in 4.4% of symptomatic subjects undergoing routine magnetic resonance imaging [3].

Symptoms

The patient will usually complain of local pain, tenderness, or swelling in the affected site. The pain is worse with flexion and usually occurs at night or after activity. The pain also may be more prominent and accompanied by stiffness on waking in the morning. Limping may or may not be present.

Physical Examination

The patient may have an antalgic gait, with a shortened stance phase on the affected side. There is discrete tenderness to

palpation associated with fullness at the site of the bursa involved, and there may be associated redness and increased temperature. If the bursa connects with the knee joint, there may be an associated effusion. There is often limited range of motion in the knee. Neurologic examination findings should be normal.

Functional Limitations

The patient may have difficulty with prolonged walking. Decreased balance is often seen in older patients, sometimes necessitating assistive devices (e.g., walker, crutches, cane, or wheelchair). If there is limitation in knee range of motion, patients may have difficulty bending the knees to drive or sitting at a desk at work. They will also have problems stooping, kneeling, crawling, or climbing, which may interfere with vocational and recreational activities. Athletes such as runners may have diminished performance or may be sidelined altogether.

Diagnostic Studies

The diagnosis is based mainly on history and clinical examination. Aspiration is rarely needed but may be necessary if an infection is suspected. Radiologic studies are usually performed to rule out other diagnoses but may show exostosis in areas related to the bursa. Ultrasound imaging may be helpful to visualize the swelling in the bursal sac and may be augmented by use of an air-steroid-saline mixture as a contrast medium [9]. Plain radiographs should be obtained if a bone tumor is suspected, particularly in patients with night pain. Arthrography, which is rarely done, may show the connection to the knee joint, if it is involved. Magnetic resonance imaging may be needed to rule out a tumor or malignant neoplasm and may show a fluid collection in the involved bursa [1,4].

Differential Diagnosis

Infection (e.g., septic knee)
 Arthritis (osteoarthritis, rheumatoid arthritis, psoriatic arthritis)
 Tumor
 Patellar fracture
 Meniscal tear
 Collateral ligament sprain or tear
 Saphenous nerve entrapment

Treatment

Initial

Restriction of activity that provokes or aggravates symptoms is important [1,4–6,10]. In athletes, this may mean a substitution of the usual athletic activities while the healing process proceeds. Local application of ice helps decrease pain and inflammation. The patient can be taught to use superficial heat for chronic bursitis. This can be done with moistened warm compresses or with a microwaveable or electric heating pad. Precautions should be observed and given to the patient to prevent burns and other complications (see section on potential treatment complications). Nonsteroidal anti-inflammatory drugs can be prescribed to decrease pain and inflammation. Oral steroids are generally not indicated as initial treatment.

Rehabilitation

Use of an orthosis in the affected knee may assist in preventing painful movement and further inflammation as

well as provide comfort. Shoe inserts unilaterally or bilaterally, depending on the pathologic process, may also lead to positively altered biomechanics of the lower extremities to improve symptoms. For example, for those individuals with associated medial compartment knee osteoarthritis, a lateral wedge insole may improve symptoms and function [11].

Formal physical therapy may address stretching of the quadriceps, hamstrings, iliotibial band, and hip adductor muscles if these muscles are tight. Strengthening exercises are often needed in chronic knee bursitis because of disuse weakness. Correction of gait abnormalities (e.g., leg length discrepancy with a heel lift, or pes planus with orthotic inserts) is also important. Patients should also be counseled to protect their knees from further trauma (e.g., by avoidance of bending or kneeling or by use of knee pads).

Modalities such as ultrasound have not been proved to be more effective than a combination of the aforementioned measures. Ultrasound should be avoided when an effusion is present because it can worsen the effusion. Phonophoresis and iontophoresis may have merit, but they are still controversial [12].

Procedures

Intrabursal corticosteroid injection is appropriate if there is no response to conservative management or if the patient demonstrates significant functional limitations (Fig. 71.2). Typically, no more than three injections are done in a 6- to 12-month period. Alternative diagnoses should be considered for patients with refractory symptoms.

FIGURE 71.2 Under sterile conditions, with use of a 1½-inch, 22-gauge needle, inject the bursa at the point of maximal tenderness. A 1- to 3-mL combination of local anesthetic and corticosteroid is used (e.g., 1 mL of 1% lidocaine mixed with 1 mL of 40mg/mL triamcinolone acetone). Local anesthetics may be injected just before the steroid to diminish pain and to prevent postinjection steroid flare [1,4–6,13]. Application of ice is helpful in decreasing pain at the site after injection.

The patient is generally advised to avoid activity involving the area injected for approximately 2 weeks to promote retention of the corticosteroid in the bursa and to avoid systemic absorption [13]. There is some evidence to suggest that persons who have pes anserine bursitis that is demonstrated with ultrasonography may have the best outcome after corticosteroid injection [14,15].

With use of a high-frequency linear ultrasound transducer along the medial aspect of the knee, a mixture of anesthetic and long-acting corticosteroid may be injected through a 25-gauge needle [16]. However, a study demonstrated that there is no additional benefit after an injection with methylprednisolone [17].

As an alternative to surgery, in cases of persistent prepatellar bursitis, chemical ablation has been used, although no robust clinical trials exist to provide evidence for its efficacy [18].

Surgery

Surgery is generally not indicated and should be undertaken only in refractory cases. Excision of a bursa can be considered if the disease does not respond to conservative measures, despite treatment, and it greatly limits the patient's activities. Successful surgical resection of bursae has been reported in the literature [19–22]. Outpatient endoscopic bursectomy under local anesthesia has been reported in a case series as an effective treatment of post-traumatic prepatellar bursitis after failed conservative management [23].

Potential Disease Complications

Possible complications include chronic pain, deconditioning, disuse muscle atrophy, and knee flexion contracture. Furthermore, this may lead to decreased walking ability and postural instability over time, especially in older adults.

Potential Treatment Complications

Potential complications from medications include drug hypersensitivity and prolonged bleeding; nonsteroidal anti-inflammatory drugs have gastric, renal, and hepatic side effects. Hyperglycemia, electrolyte imbalance, and gastric irritation or ulceration from intrabursal steroid injection are not as common as with orally administered corticosteroids but can still occur from systemic absorption of the injectant. Local ice application may produce hypersensitivity and vasoconstriction in patients with Raynaud disease and peripheral vascular disease, and local heat application may produce burns, sedation, skin discoloration, and vascular compromise. Moreover, injections may result in drug hypersensitivity, sterile abscess, infection, nerve injury, tendon rupture, and lipoatrophy from intralesional steroids

[13,14]. Furthermore, a case of patella tendon rupture has been reported after arthroscopic resection of the prepatellar bursa [24].

Definition

The menisci serve important roles in maintaining proper joint health, stability, and function [1]. The anatomy of the medial and lateral menisci helps explain functional biomechanics. Viewed from above, the medial meniscus appears C shaped and the lateral meniscus appears O shaped (Fig. 72.1)[1]. Each meniscus is thick and convex at its periphery (the horns) but becomes thin and concave at its center. This contouring serves to provide a larger area for the rounded femoral condyles and the relatively flat tibia. Menisci do not move in isolation. They are connected by ligaments to each other anteriorly and to the anterior cruciate ligament, the patella, the femur, and the tibia [2,3].

The medial meniscus is less mobile than the lateral meniscus. This is due to its firm connections to the knee joint capsule and the medial collateral ligament. This decreased mobility, in conjunction with the fact that the medial meniscus is wider posteriorly, is cited as the usual reason for the higher incidence of tears within the medial meniscus than within the lateral meniscus [1]. The semimembranosus muscle (through attachments from the joint capsule) helps retract the medial meniscus posteriorly, serving to avoid entrapment and injury to the medial meniscus as the knee is

flexed [3]. The lateral meniscus is not as adherent to the joint capsule. Unlike the medial meniscus, the lateral meniscus does not attach to its respective collateral ligament. The posterolateral aspect of the lateral meniscus is separated from the capsule by the popliteus tendon. Therefore the lateral meniscus is more mobile than the medial meniscus [1,3]. The attachment of the popliteus tendon to the posterolateral meniscus ensures dynamic retraction of the lateral meniscus when the knee internally rotates to return out of the screw-home mechanism [2]. Therefore both the medial and the lateral menisci, by having attachments to muscle structures, share a common mechanism that helps avoid injury.

The architecture of the vascular supply to the meniscus has important implications for healing [1,4]. Capillaries penetrate the menisci from the periphery to provide nourishment. After 18 months of age, as weight bearing increases, the blood supply to the central part of the menisci recedes. In fact, research has shown that eventually only the peripheral 10% to 30% of the menisci, or the red zone, receives this capillary network (Fig. 72.2) [5]. Therefore the central and internal portion or white zone of these fibrocartilaginous structures becomes avascular with age, relying on nutrition received through diffusion from the synovial fluid. Because of this vascular arrangement, the peripheral meniscus is more likely to heal than are the central and posterolateral aspects [4].

The primary but not sole function of the menisci is to distribute forces across the knee joint and to enhance stability [1,6–8]. Multiple studies have shown that the ability of the joint to transmit loads is significantly reduced if the meniscus is partially or wholly removed [1,6,7,9]. Fairbank [10] published a seminal article in 1948 suggesting that the menisci are vital in protecting the articular surfaces. He reported that individuals who had undergone total meniscectomies demonstrated premature osteoarthritis.

Meniscal tears are classified by their complexity, plane of rupture, direction, location, and overall shape. Tears are commonly defined as vertical, horizontal, longitudinal, or oblique in relation to the tibial surface (Fig. 72.3)[11]. Most meniscal tears in young patients will be vertical-longitudinal,

FIGURE 72.1 Superior view of medial and lateral menisci.

FIGURE 72.2 Vascular zones of the meniscus. Tears within the red zone have a higher healing potential.

FIGURE 72.3 Types of meniscal tears.

whereas horizontal cleavage tears are more commonly found in older patients [12]. The bucket-handle tear is the most common type of vertical (or longitudinal) tear [13] (Fig. 72.4). Tears are also described as complete, full-thickness or partial tears. Complete, full-thickness tears are so named as they extend from the tibial to femoral surfaces. In addition, medial meniscus tears outnumber lateral meniscus tears from 2:1 to 5:1 [14,15].

FIGURE 72.4 Bucket-handle type of meniscal tear.

Meniscal injuries may result from an acute injury or from gradual degeneration with aging [16]. Vertical tears (e.g., bucket-handle tears) tend to occur acutely in individuals 20 to 30 years of age and are usually located in the posterior two thirds of the meniscus [13,17]. Sports commonly associated with meniscal injuries are soccer, football, basketball, baseball, wrestling, skiing, rugby, and lacrosse. Injury commonly occurs when an axial load is transmitted through a flexed or extended knee that is simultaneously rotating [16]. Degenerative tears, in contrast, are usually horizontal and are seen in older individuals with concomitant degenerative joint changes [13,18].

On the basis of arthroscopic examination, the majority of acute peripheral meniscal injuries are associated with some degree of occult anterior cruciate ligament laxity [19]. In addition, true anterior cruciate ligament tears are associated with lesions of the posterior horns of the menisci [19]. Lateral meniscal tears appear to occur with more frequency with acute anterior cruciate ligament injuries, whereas medial meniscal tears have a higher incidence with chronic anterior cruciate ligament injuries. With chronic anterior cruciate ligament injuries, the medial meniscus may be more frequently damaged because its posterior horn serves as an important secondary stabilizer of anterior-posterior instability [20].

Symptoms

The history will help diagnose a meniscal injury 75% of the time [12,21]. Young patients who experience meniscal tears will recall the mechanism of injury 80% to 90% of the time and may report a “pop” or a “snap” at the time of injury. Deep knee bending activities are often painful, and mechanical locking may be present in 30% of patients [22]. Bucket-handle tears should be suspected in cases of mechanical locking with loss of full extension [16]. If locking is reported approximately 1 day after the injury, this may be due to “pseudolocking,” which results from hamstring contracture [14]. Knee hemarthrosis may also occur acutely, especially if the vascularized, peripheral portion of the meniscus is involved. In fact, 20% of all acute traumatic knee hemarthroses are caused by isolated meniscal injury [23]. More typically, however, knee swelling occurs approximately 1 day later as the meniscal tear causes mechanical irritation within the intra-articular space, creating

FIGURE 72.5 McMurray test. **A**, Starting position for testing of the medial meniscus. The knee is acutely flexed, with the foot and tibia in external rotation. **B**, Starting position for testing of the lateral meniscus. The knee is acutely flexed, and the foot and tibia are internally rotated. **C**, Ending position for the lateral meniscus. The knee is brought into extension while rotation is maintained. Ending position for the medial meniscus is the same but with the external rotation. If pain or a “clunk” is elicited, the test result is considered positive. (From Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

a reactive effusion. Typically, this effusion is secondary to a lesion in the central portion of the meniscus [16].

In contrast, degenerative meniscal tears are not usually associated with a history of trauma. In fact, the mechanism of injury, which may not be reported by the patient, can be simple daily activities, such as rising from a chair and pivoting on a planted foot [16]. Patients with degenerative tears often also report recurrent knee swelling, particularly after activity.

Physical Examination

Physical examination aids the accurate diagnosis of a meniscal injury in 70% of patients [24]. Gait evaluation may reveal an antalgic gait with decreased stance phase and knee extension on the symptomatic side [23]. A knee effusion is observed in about half of individuals with a known meniscal tear [25]. Quadriceps atrophy may be noted a few weeks after injury. Palpation of the joint line frequently results in tenderness. Posteromedial or lateral tenderness is most suggestive of a meniscal tear [12]. The result of a “bounce home” test may be positive. This test result is positive when pain or mechanical blocking is appreciated as the patient’s knee is passively forced into full extension [14]. The result of the McMurray test is positive 58% of the time in the presence of a tear but is also reported to be positive in 5% of normal individuals (Fig. 72.5) [13]. The Apley compression test is an insensitive indicator of meniscal injury. With this test, the prone knee is flexed to 90 degrees and an axial load is applied (Fig. 72.6). A painful response is considered a confirmatory test result with a reported sensitivity of 45% [23]. A dynamic functional test known as the Thessaly maneuver can detect a meniscal tear [26]. This maneuver is performed while the patient stands with the affected knee flexed at either 5 degrees or 20 degrees and internally or externally rotates the body. The test result is considered suggestive of a meniscal tear if there is reproduction of joint line discomfort or if clicking or locking is noted [26]. No singular meniscal provocation test has been shown to be predictive of meniscal injury compared with findings on arthroscopy. Physical examination findings become even less reliable in patients with concomitant anterior cruciate ligament deficiencies [14,27]. Neurologic examination

findings, including sensation and deep tendon reflexes, should be normal unless there is associated guarding due to pain or diffuse weakness, particularly with knee extension (quadriceps muscle inhibition).

Functional Limitations

Patients with meniscal injuries may have difficulty with deep knee bending activities, such as traversing stairs, squatting, or toileting. In addition, jogging, running, and even walking may become problematic, particularly if any rotational component is involved. Laborers who repetitively squat may report mechanical locking with loss of full knee extension on rising.

Diagnostic Studies

Standing plain radiographs are usually normal in isolated meniscal injuries. Presence of osteoarthritis, as with degenerative meniscal tears, can be detected with weight-bearing anteroposterior and lateral knee films. With nondegenerative tears, magnetic resonance imaging (MRI) has largely replaced plain radiographic examination in detecting injury;

FIGURE 72.6 Apley compression test. The patient is prone. The examiner applies pressure on the sole of the foot toward the examination table. The tibia is internally and externally rotated. (From Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

however, meniscal tears can be present in asymptomatic individuals [12,28]. Sagittal views demonstrate the anterior and posterior horns of the menisci; coronal images can be vital in diagnosis of bucket-handle and parrot-beak tears [1,14]. There are three grades of meniscal injury as determined by the location of T2 signal intensity within the black cartilage. By definition, only grade 3 tears qualify as true meniscal tears; however, a few grade 2 lesions seen on MRI will be found to be true tears on arthroscopy (Fig. 72.7) [29]. With use of arthroscopy as the “gold standard,” the sensitivity of MRI varies from 64% to 95%, with an accuracy of 83% to 93% [16]. MRI appears to have a false-positive rate of 10% [1,24]. A 5% false-negative rate is also reported and may be due to missed tears at the meniscosynovial junction [30]. Ultrasonography has also been used to diagnose meniscal tears but with lower specificity compared with MRI [31].

Interestingly, despite the recent accessibility and advancement in ultrasonography and MRI, clinical examination by experienced physicians is cheaper and appears to be as accurate as MRI for the diagnosis of meniscal tears [29,32]. However, MRI may be particularly helpful when history and physical examination findings are equivocal and the physician is required to establish an expedient diagnosis [13,23].

Differential Diagnosis

Anterior or posterior cruciate ligament tear
Medial collateral ligament tear
Osteoarthritis
Plica syndromes
Popliteal tendinitis
Osteochondritic lesions
Loose bodies
Patellofemoral pain
Fat pad impingement syndrome
Inflammatory arthritis
Physal fracture
Tumors

Treatment

Initial

The truly locked knee resulting from a meniscal tear should be reduced within 24 hours of injury. Otherwise, acute tears of the meniscus may initially be treated with rest, ice, and compression, with weight bearing as tolerated. Patients may need to use crutches acutely. A knee splint may be applied for comfort of the patient, particularly in unstable knees with underlying ligamentous injury [22].

Analgesics such as acetaminophen or opioids can be used for pain. Nonsteroidal anti-inflammatory drugs can be used for pain and inflammation.

Arthrocentesis can be performed (ideally in the first 24 to 48 hours) for both diagnostic and treatment purposes when there is a significant effusion.

Rehabilitation

Not all meniscal injuries necessitate surgical intervention or resection. In fact, some meniscal lesions have gradual resolution of symptoms during a 6-week period and may have normal function by 3 months [11]. Types of tears that may be treated with nonsurgical measures include partial-thickness longitudinal tears, small (<5 mm) full-thickness peripheral tears, and minor inner rim or degenerative tears [33]. Healing potential is greatest for tears within the red zone [34]. In general, only meniscal injuries that are persistently symptomatic should be referred for surgical intervention.

Both nonsurgical and partial meniscectomy patients undergo similar rehabilitation protocols. Crutches may be used to off-load the affected limb. These can usually be discontinued when patients are ambulating without a limp [35]. The goal during the first week is to decrease pain and swelling while increasing range of motion and muscle strength and endurance. Institution of static strengthening in conjunction with electrical stimulation can retard quadriceps atrophy [30]. Aerobic conditioning can begin as long as the patient can tolerate bicycle training or aqua jogging. As time progresses,

FIGURE 72.7 MRI grading of meniscal tears. **A**, Poorly defined “globular” zone of increased signal intensity (arrow), corresponding to grade 1 change. **B**, Linear zone of hyperintensity (arrow) not communicating with the articular surfaces, corresponding to grade 2 change. **C**, Linear band of hyperintensity (arrow) communicating with both articular surfaces, corresponding to grade 3 change, that is, a complete tear. (From Mellion MB. *Office Sports Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 1996.)

a combination of open and closed kinetic chain exercises in all three planes (sagittal, coronal, and transverse) can be performed in conjunction with stretching of the lower limb. Gradually, during the ensuing weeks, more functional activities are introduced. More challenging proprioceptive and balancing activities also can be started as deemed appropriate. Finally, plyometric training is begun, and the individual is gradually introduced back into sport-specific activities.

Multiple rehabilitation protocols for the surgically repaired meniscus have been described. Rehabilitation programs ideally need to be individualized to the specific type of repair performed. In addition, there has been considerable controversy among physicians about the patient's weight-bearing and immobilization status soon after surgical repair [30,36–39]. In general, however, initial exercises are nonaggressive, avoiding dynamic shear forces that may occur from joint active range of motion. Therefore, exercises are initially static, targeting hip abductors, adductors, and extensors. Static quadriceps exercises are performed with care to avoid terminal knee extension. While superior and medial patella mobilization is begun, stretching of the lower limb musculature in multiple planes is emphasized. After 2 to 3 weeks, goals are to increase range of motion and to advance weight-bearing status while a resistance exercise program is introduced. With the absence of effusion and significant pain, improved knee range of motion from 5 to 110 degrees should be achieved. More aggressive active range of motion may be started, particularly if the repair was to the outer peripheral or vascular zone of the meniscus because the success rate for healing here is higher [30]. Gradually, more functional activities with use of resistive bands may be introduced. With time and success of the patient, resistance can be increased and proprioceptive neuromuscular facilitation activities can be implemented, ensuring that the individual is rehabilitated in the coronal, transverse, and sagittal planes [40].

Brace protection, if it was initially employed, may be discontinued, particularly when the patient demonstrates success with proprioceptive testing. Running, cutting, and rotational activities are avoided. However, sport-specific exercises can be initiated when no effusion exists, knee strength is at least 70% of normal, and the knee can attain full range of motion [39]. Athletes may be able to return to their individual activities at about 16 weeks for those with repairs in the vascular zone and 24 weeks for those with repairs in the nonvascular zone.

Procedures

Patients presenting after an acute injury with an effusion may benefit from a joint aspiration, not only to help relieve discomfort and stiffness but also to aid in discerning whether a hemarthrosis or marrow fat (to rule out an occult fracture) is present.

Surgery

Specific types of tears may not require surgical repair; these include longitudinal partial-thickness tears, stable full-thickness peripheral tears (<5 mm long), and short (<5 mm) radial tears [35]. These are usually stable and

may not require either suture fixation or immobilization. However, arthroscopy may still be necessary to determine stability and to stimulate healing through perimeniscal abrasion [11].

Some larger longitudinal, radial, and degenerative meniscal tears are less likely to heal without surgical intervention. Although first-line treatment of these lesions is aggressive rehabilitation, recalcitrant cases may require a partial meniscectomy that preserves as much of the meniscus as possible [37]. In addition, the inner aspect of the cartilage, which may be ragged, may be rasped or shaved, providing a smooth surface that eliminates mechanical symptoms.

On occasion, other tears of the menisci, because of their size and location, are best treated by primary approximation with sutures and primary repair [41]. Typically, longitudinal tears longer than 5 mm in the periphery of the meniscus are best suited for this because they have a high rate of successful healing [35]. In older individuals, the mere presence of a horizontal or degenerative cleavage tear is insufficient to justify removal because these meniscal portions may still participate in significant load transmission but not necessarily cause symptoms [11]. Treatment of these degenerative tears is usually nonsurgical; however, unstable portions may be removed during arthroscopy. Good outcomes have been documented after patients with degenerative tears have been treated with aggressive rehabilitation [42].

Potential Disease Complications

Once a meniscal tear occurs, the joint inherently becomes less stable. This instability may promote further extension of the initial tear, turning a nonsurgical lesion into one in which arthroscopic repair may be necessary. Chronically, the resultant increased abnormal motion that occurs secondary to the meniscal injury may also lead to damage of the articular surface and predispose to premature osteoarthritis [12].

Potential Treatment Complications

Analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs have well-known side effects that may affect the gastric, hepatic, and renal systems. An overly aggressive regimen may lead to extension of the tear or failure of the meniscus to heal. A rehabilitative program that is too conservative, in contrast, may also lead to a significant loss of strength with muscle atrophy and decreased range of motion. If the surgical approach resulted in a significant amount of cartilage removed, the knee may be predisposed to development of osteoarthritis as originally described by Fairbank [10]. Saphenous nerve injuries as well as infections are also common complications after meniscal repair surgery and arthroscopy [12].

CHAPTER 73

Patellar Tendinopathy (Jumper's Knee)

Rathi L. Joseph, DO
Joseph T. Alleva, MD, MBA
Thomas H. Hudgins, MD

Synonyms

Patellar tendinitis
Quadriceps tendinitis
Patellar tendinosis
Patellar apicitis
Partial rupture of patellar ligament

ICD-9 Code

726.64 Patellar tendinitis

ICD-10 Codes

M76.50 Patellar tendinitis, unspecified knee
M76.51 Patellar tendinitis, right knee
M76.52 Patellar tendinitis, left knee

Definition

Patellar tendinopathy or “jumper’s knee,” first described by Blazina and colleagues [1] in 1973, is primarily a chronic overuse injury of the patellar tendon resulting from excessive stress on the knee extensor mechanism. Athletes involved in sports requiring repetitive jumping, running, and kicking (e.g., volleyball, basketball, tennis, track) are at greatest risk. For example, volleyball players have an increased incidence compared with other sports of 22% to 39% [2]. Acceleration, deceleration, takeoff, and landing generate eccentric forces that can be three times greater than conventional concentric and static forces. These eccentric forces may exceed the inherent strength of the patellar tendon, resulting in microtears anywhere along the bone-tendon interface [2–4]. With continued stress, a cycle of

microtearing, degeneration, and regeneration weakens the tendon and may lead to tendon rupture.

As in other overuse injuries, the predisposing factors in jumper’s knee include extrinsic causes, such as errors in training, and intrinsic causes, such as biomechanical flaws. Training errors include improper warm-up or cool-down, rapid increase in frequency or intensity of activity, and training on hard surfaces [3,4]. Biomechanical imbalances, such as tight hamstrings and excess femoral anteversion [3], and jumping mechanics [2,5] have been implicated as increased risk factors for development of patella tendinopathy (jumper’s knee). Finally, an increased incidence of Osgood-Schlatter disease and idiopathic anterior knee pain during adolescence has been identified in patients with jumper’s knee [3].

Because histologic studies of the patellar tendon reveal collagen degeneration with little or no evidence of acute inflammation, many authors argue that “patellar tendinopathy or tendinosis” is a more accurate description than “patellar tendinitis.” [6–8] This distinction has important implications for rehabilitation. In treatment of patellar tendinosis and other chronic overuse tendinopathies, the treatment team should emphasize restoration of function rather than control of inflammation. This is an overuse syndrome that has no age or gender predilection.

Symptoms

Patients typically report a dull, aching anterior knee pain, initially noted after a strenuous exercise session or competition, that is insidious in onset and well localized [7]. The bone-tendon junction at the inferior pole of the patella is most frequently affected (65% of cases), followed by the superior pole of the patella (25%) and the tibial tubercle (10%) [6]. Other symptoms may include stiffness or pain after prolonged sitting or climbing stairs [3], a feeling of swelling or fullness over the patella, and knee extensor weakness [1]. Mechanical symptoms of instability, such as locking, catching, and give-way weakness, are uncommon.

Four phases have been described in the progression of jumper's knee: phase 1, pain is present after activity only and is not associated with functional impairment; phase 2, pain is present during and after activity but does not limit performance and resolves with rest; phase 3, pain is present continually and is associated with progressively impaired performance; and phase 4, complete tendon rupture [1].

As the disease progresses, the pain becomes sharper, more severe, and constant (present not only with athletic endeavor but also with walking and other everyday activities). If it is not treated, the disorder may result in tendon rupture, a sudden painful event associated with immediate inability to extend the knee [7].

Physical Examination

The hallmark of jumper's knee is tenderness at the site of involvement, usually the inferior pole of the patella [7]. This sign is best elicited on palpation of the knee in full extension [7], and the pain typically increases when the knee is extended against resistance [3]. On occasion, there may be swelling of the tendon or the fat pad, although a frank knee joint effusion is not typically present [3]. Mild patellofemoral crepitus and pain with compression of the patellofemoral joint have been noted [3]. In advanced disease, patients may have quadriceps atrophy without detectable weakness on manual muscle testing and hamstring tightness [3,7]. Test results for knee ligamentous laxity are negative. The examiner should also expect normal findings on neurologic examination.

Functional Limitations

Most patients experience little functional limitation in the early stages of jumper's knee. As the disease progresses, however, increasing disability from persistent pain and inhibition of knee extension impairs athletic performance. Eventually, walking and the ability to perform basic activities of living, such as ascending or descending stairs, may be compromised. In the event of patellar tendon rupture, complete functional impairment with inability to extend the affected knee, limiting weight bearing and ambulation, necessitates surgical repair.

Diagnostic Testing

Radiographic changes are rarely present during the first 6 months of patellar tendinopathy, limiting the usefulness of radiographs during initial evaluation [4]. When radiography is performed, the examination generally includes anteroposterior, lateral, intercondylar, and skyline (or sunrise) tracking patellar views [3]. Documented findings include radiolucency at the site of involvement, elongation of the involved pole, and occasionally a fracture at the junction of the elongation with the main portion of the patella. On occasion, calcification of the involved tendon and irregularity or even avulsion of the involved pole may be seen [1].

Ultrasonography has the advantage of allowing early diagnosis and dynamic imaging of the tendon while remaining inexpensive, noninvasive, reproducible, and sensitive to changes as small as 0.1 mm [4]. Some authors believe ultrasonography to be the preferred method for evaluation

of jumper's knee. It has been used to confirm the diagnosis, to guide steroid injections, and to observe tendons after surgery [4]. It should be considered in cases that do not respond to a trial of conservative treatment after 4 to 6 weeks and when the diagnosis is questioned. Findings on ultrasound examination include thickening of the tendon [4,9]. A hypoechoic focal lesion at the area of greatest thickening correlates well with the lesion on magnetic resonance imaging (MRI), computed tomography, and histologic examination [3,10]. However, critics of ultrasonography have noted abnormalities in asymptomatic athletes. This phenomenon may be explained by a preclinical or postclinical stage of the disease [4]. Plain MRI, MRI with intravenous administration of gadolinium, and MRI arthrography with gadolinium have been used to corroborate the clinical diagnosis of jumper's knee. Increased thickening of the patellar tendon on MRI is present in all patients resistant to conservative therapy [11,12]. MRI is also advantageous in excluding other intrinsic joint disease. MRI arthrography is particularly useful in examining the chondral surfaces of the patella and femur when osteochondritis dissecans or other pathologic processes in these areas are suspected. Before advanced imaging, we recommend simple radiographic examination with three views of the knee to rule out bone pathologic changes and to evaluate joint space. If patients do not respond to physical therapy in 4 to 6 weeks, ultrasound examination is the preferred study at that time to confirm the diagnosis.

Differential Diagnosis

- Patellofemoral maltracking
- Retinacular pain
- Fat pad lesion
- Lipoma arborescens
- Infrapatellar bursitis
- Partial anterior cruciate ligament tear
- Meniscal injuries
- Chondromalacia patellae
- Plica syndrome
- Entrapment of the saphenous nerve
- Osgood-Schlatter lesion
- Sinding-Larsen-Johansson syndrome [3,4,7]

Treatment

Initial

Because the syndrome is progressive and associated with difficult and slow rehabilitation, the importance of early diagnosis and treatment cannot be overemphasized [13]. Initial interventions include control of pain with nonsteroidal anti-inflammatory drugs, ice, and relative rest. Passive modalities such as ultrasound and iontophoresis with corticosteroid preparation are also used judiciously to control pain.

Rehabilitation

A comprehensive rehabilitation program should address the biomechanical flaws found on the musculoskeletal examination. These include the functional deficits (inflexibilities that lead to altered biomechanics) and subclinical adaptations

(substitution patterns that compensate for the functional deficits) [14]. This approach may be used in addressing all overuse syndromes. In patellar tendinopathy, hamstring and quadriceps tightness and weakness need to be addressed [14]. As the rehabilitation program advances and pain abates, eccentric strengthening exercises should be emphasized. This type of strengthening exercise is optimal for rehabilitation of tendinopathies because it places maximal tensile load on the muscle and tendon unit (Fig. 73.1) [15]. There is a paucity of randomized controlled studies supporting this type of exercise; however, eccentric strengthening is commonly recommended [16]. This type of exercise may provoke pain initially, given the increased load placed on the muscle-tendon unit. The final phase of rehabilitation should also encompass sports-specific drills and training. Knee supports and counterforce straps have been used to alleviate pain and to change the force dynamics through the patellar tendon with good results [4,17].

FIGURE 73.1 Eccentric strengthening, right quadriceps.

Procedures

Some authors recommend a peritendinous injection of steroid if noninvasive conservative therapy fails [3,4]. This is performed with ultrasound guidance to ensure accurate placement of the needle. Decreased pain with injection of the fat pad rather than of the tendon itself has been documented [3]. Because histologic studies have shown a minimal inflammatory component in surgical specimens, the mechanism of action of these approaches is unknown [4]. In addition, studies have associated tendon ruptures with steroid injection [4,18]. The efficacy of prolotherapy (10% dextrose) in patellar tendinopathy has not been studied [19]. Some anecdotal evidence supports the use of protein-rich plasma therapy [20].

Surgery

In the advanced stage of jumper's knee, if a well-documented conservative therapy trial has failed or if the tendon ruptures, surgery is indicated. Several approaches have had mixed success; resection of the tendon disease with resuturing of the tendon is most often cited, and authors report 77% to 93% good or excellent results [21,22].

However, when more invasive treatments, such as injections or surgery, are contemplated, it is incumbent on the practitioner to ensure that a comprehensive rehabilitation program has been followed thoroughly, as outlined earlier, before one declares a "conservative management failure." Criteria for conservative management failure are often ill-defined in the literature. In our experience, invasive procedures are rarely necessary for the management of jumper's knee. Postoperative rehabilitation begins with isometric strengthening of the quadriceps, restoring range of motion and advancing to eccentric strengthening in 6 to 12 weeks.

Potential Disease Complications

Stress reaction of the patella, stress fracture, and patellar tendon rupture are some of the advanced complications. Others include formation of accessory ossicles, avulsion apophysis, and bone growth acceleration or arrest in adolescents [23].

Potential Treatment Complications

Gastrointestinal bleeding and renal side effects of non-steroidal anti-inflammatory drugs are well documented. Complications of corticosteroid injections include bleeding, infection, and soft tissue atrophy at the site of injection. Tendon weakening with possible increased incidence of tendon rupture has also been cited. Surgery can lead to inadvertent tibial or peroneal nerve injury.

Definition

Patellofemoral syndrome is the most common ailment involving the knee in both the athletic and the nonathletic population [3–5]. In sports medicine clinics, 25% of patients complaining of knee pain are diagnosed with this syndrome, and it affects women twice as often as men [3]. Yet despite the common occurrence of this disorder, there is no clear consensus on the definition, etiology, and pathophysiology [6]. The most common theory is that the syndrome is an overuse injury from repetitive overload at the patellofemoral joint. This increased stress results in physical and biomechanical changes of the patellofemoral joint [6]. The literature has focused on identification of risk factors leading to altered biomechanics that produce poor patellar tracking in the femoral trochlear groove and thus stress at the patellofemoral joint. Possible pain generators include the subchondral bone, retinacula, capsule, and synovial membrane [7]. Historically, the histologic diagnosis of chondromalacia, or deterioration of the cartilage, had been associated with patellofemoral syndrome. However, chondromalacia is poorly associated with the incidence of patellofemoral syndrome [5]. Electromyographic comparison of vastus medialis oblique (VMO) to vastus lateralis activation has shown delayed VMO activation in those patients with patellofemoral syndrome [8]. A pilot investigation has been done with 64-channel surface electromyography and motion capture to evaluate activation of the four heads of the quadriceps muscle in three dimensions. That study showed increased

variability in the pattern of activation in the patellofemoral group compared with controls, resulting in altered patellar kinematics and loading of the patellar facets [9].

Symptoms

The patient with patellofemoral syndrome will complain of diffuse, vague ache of insidious onset [3]. The anterior knee is the most common location for pain, but some patients describe posterior knee discomfort in the popliteal fossa [4]. The discomfort is aggravated by prolonged sitting with knees flexed (“theater” sign) as well as on ascending or descending of stairs and squatting because these positions place the greatest force on the patellofemoral joint [10]. The patient may also experience pseudolocking when the knee momentarily locks in an extended position [11,12].

Physical Examination

The examination focuses on identification of risk factors that contribute to malalignment and rules out other pathologic processes associated with anterior knee pain. Tenderness to palpation at the medial and lateral borders of the patella may be appreciated [3]. A minimal effusion may also be present. The results of manual testing for intra-articular disease, such as the Lachman (anterior cruciate ligament) and McMurray (meniscal) maneuvers, will be negative.

The presence of femoral anteversion, tibia internal rotation, excessive pronation at the foot, increased Q angle, and inflexibility of the hip flexors, quadriceps, iliotibial band, and gastrocnemius-soleus should be determined [13]. The patella position (baja or alta, internal or external rotation) should also be assessed with the patient sitting and standing. Each of these factors has either a direct or an indirect influence on the tracking of the patella with the femur (Fig. 74.1).

FIGURE 74.1 Forces on the patella in patellofemoral syndrome.

The Q angle is the intersection of a line from the anterior superior iliac spine to the patella with a line from the tibial tubercle to the patella (Fig. 74.2). This angle is typically less than 15 degrees in men and less than 20 degrees in women. An increased angle is associated with increased femoral anteversion and thus patellofemoral joint torsion [11]. However, a consensus on the importance of an increased Q angle is lacking [6]. Tight hip flexors, quadriceps, hamstrings, and gastrocnemius-soleus will increase knee flexion and thus patellofemoral joint reaction force. A tight iliotibial band will increase the lateral pull of the patella through the lateral retinacular fibers [14,15]. Static hip strength was not shown to be a predisposing component of patellofemoral syndrome pain in women [16]. It is imperative to assess each of these components in the lower extremity kinetic chain to prescribe a tailored physical therapy program for each individual (Table 74.1).

FIGURE 74.2 Measurement of Q angle. A line is drawn from the anterior iliac spine to the center of the patella. A second line is drawn from the center of the patella to the tibial tubercle. An angle between these two lines is called the Q angle.

Table 74.1 Causes of Altered Biomechanics

Altered Biomechanics	Etiology
Increased knee flexion	Tight hip flexors, quadriceps, hamstrings, gastrocnemius-soleus
Lateral pull of patella	Tight iliotibial band, weak vastus medialis oblique
Femoral anteversion	Increased Q angle
Tibial internal rotation	Excessive foot pronation

Functional Limitations

The patient with the patellofemoral syndrome will avoid activities that provoke the discomfort initially, such as stair climbing. Prolonged sitting in a car may be difficult. In chronic, progressive cases, ambulation may be enough to incite the pain, making all activities of daily living difficult.

Diagnostic Testing

Patellofemoral syndrome is a clinical diagnosis. Plain films may be used to evaluate Q angle and patella alta or baja. Advanced imaging, such as magnetic resonance imaging, is reserved for recalcitrant cases that do not respond to conservative care to rule out intra-articular disease. Bone scintigrams revealed diffuse uptake in the patellofemoral joint in 50% of patients diagnosed with patellofemoral syndrome [17].

Differential Diagnosis

- Patella fracture
- Patella dislocation
- Quadriceps rupture
- Patella tendinitis
- Peripatellar bursitis
- Osgood-Schlatter disease
- Meniscal lesions
- Ligamentous lesions
- Plica syndromes
- Osteochondritis dissecans

Treatment

Initial

As in other overuse injuries, the initial treatment focuses on decreasing pain. Icing is beneficial, particularly after activities. Nonsteroidal anti-inflammatory drugs may be used in a judicious manner. Relative rest with non-weight-bearing aerobic activity may also be necessary. A neoprene knee sleeve with patella cutout is helpful to increase proprioceptive feedback. McConnell's taping method can be used during the acute phase to reduce pain and to increase tolerance of a therapeutic exercise program, although it was less effective in patients with higher body mass index, larger lateral patellofemoral angle, and smaller Q angles [15,18–21]. Patella bracing was shown to reduce pain and to improve function in patients with patellofemoral syndrome but no more successfully than therapeutic exercise [22]. Of patients who had lower pain levels, wore less supportive footwear, had decreased ankle dorsiflexion range of motion, and reported an immediate reduction in pain when performing a single-leg squat with a foot orthosis, 78% found relief using foot orthoses at 12 weeks. In the same study, immediate pain relief while performing a single-leg squat with orthosis use was the greatest predictor of noncustomized prefabricated foot orthosis-related pain relief at 12 weeks [23].

Rehabilitation

With no consensus on the etiology and pathophysiology of patellofemoral syndrome, numerous treatment protocols and therapies have been proposed in the literature [24]. Nevertheless, most patients respond to a directed re-

habilitation approach with therapeutic exercise [14,15]. The rehabilitation program should address deficiencies in strength, flexibility, and proprioception. Strength training can be achieved with both open kinetic chain and closed kinetic chain exercises. Open kinetic chain exercises occur when the distal link, the foot, is allowed to move freely in space, as in leg extensions. During closed kinetic chain exercises, the foot maintains contact with the ground, resulting in a multiarticular closed kinetic exercise, as in squatting or leg press [15]. Closed kinetic chain exercises are also less stressful than open chain exercises at the patellofemoral joint in the functional range of 0 to 45 degrees of knee flexion [25].

These exercises can be performed in multiple planes in a "functional" rehabilitation program (Figs. 74.3 and 74.4). This may entail having the patient perform a lunge (a closed kinetic chain exercise) in the coronal, sagittal, and transverse planes, simulating positions applied during activities. These exercises can also stress the patient's balance by performance of the lunges with eyes closed. Through this functional or skill training, the patient is being prepared for all functional tasks by achieving efficient nerve-muscle interactions [10].

Many studies have focused on selective strengthening of the VMO as a dynamic medial stabilizer on the patella. Selective VMO strengthening may be achieved with combined hip adduction because the fibers of the VMO originate on the adductor magnus tendon and, to a lesser extent, the adductor longus. However, attempts at proving isolated recruitment of the VMO in relation to the vastus lateralis have failed [3]. Biofeedback and comprehensive McConnell-based physical therapy have been shown to improve motor control of the VMO as evidenced by altered firing patterns [26,27]. Nevertheless, quadriceps strengthening in general should be incorporated in the rehabilitation program through closed kinetic chain and functional exercises, which need to be incorporated in a long-term maintenance program.

Procedures

Injections are not indicated because this is primarily a mal-tracking phenomenon without a clear consensus on the pain generator.

Surgery

Surgery is rarely indicated, and a directed rehabilitation program is often successful [4]. However, several techniques have been illustrated in the literature. These include lateral retinacular release to decrease the lateral force, proximal and distal realignment procedures, and elevation of the tibial tubercle [1].

Potential Disease Complications

Recalcitrant chronic cases of anterior knee pain may show progressive degenerative changes at the patellofemoral joint, such as severe (grade IV) chondromalacia patellae.

Potential Treatment Complications

Risks of chronic use of nonsteroidal anti-inflammatory drugs include gastrointestinal bleeding, renal toxicity, hypertension, and other cardiovascular complications; thus, duration should

FIGURE 74.3 Skill training can help resolve anterior knee pain by improving strength and neuromuscular coordination. The lunge (A), step-down (B), and knee bend (C) are examples of force-absorbing skill-training exercises that are particularly valuable for improving strength, which in turn promotes stability. For the most benefit during the knee bend, the patient's knee should be aligned with the shoelaces.

FIGURE 74.4 The standing cable column is an example of a skill-training exercise. The patient uses strength to exercise against resistance offered by a cable and simultaneously refines balancing skills.

be kept to a minimum. Systemic complication risk may be lessened by application of topical nonsteroidal anti-inflammatory drugs to the affected area only.

Overcompensation for the malalignment may occur with surgical techniques such as the lateral retinacular release. The surgeon may lyse too many fibers, leading to increased medial tracking. Many of the realignment procedures should also be reserved for the skeletally mature patient [1].

 M21.379 Foot drop, unspecified foot

Definition

Peroneal neuropathy, the most common entrapment neuropathy of the lower extremity [1], is compromise of any portion of the peroneal nerve. This can be from its origins within the sciatic nerve, in which it remains distinct from the tibial portion, throughout the course of the sciatic nerve, to its terminations in the leg and foot. The common peroneal nerve completely separates from the tibial nerve in the upper popliteal fossa and then traverses laterally to

curve superficially around the fibular head. Before the fibular head, the lateral cutaneous nerve of the calf branches off to supply cutaneous sensation to the upper lateral leg. Near the fibular head, the common peroneal nerve bifurcates into the superficial peroneal nerve and deep peroneal nerve, which describes their relative locations as they wrap around the fibular head. Because the deep portion is immediately adjacent to the hard bony surface, it is more susceptible to compression injuries at the fibular head, which is the most common site of peroneal nerve compromise [2,3].

The common peroneal nerve provides the lateral cutaneous nerve of the calf and the motor branch to the short head of the biceps femoris above the fibular head. The superficial peroneal nerve is predominantly sensory, providing cutaneous sensation to the lateral lower leg and most of the foot dorsum. The superficial peroneal nerve also innervates the foot evertors, peroneus longus and brevis. The deep peroneal nerve is predominantly motor, innervating the foot and toe dorsiflexors, but it has a small cutaneous representation at the dorsal first web space of the foot.

Predisposing factors for peroneal mononeuropathy at the fibular head, the most common site of compromise, include weight loss [2,4–7], diabetes [2,8], peripheral polyneuropathy [2], and positioning and localized prolonged pressure [9], such as habitual leg crossing [1] or prolonged squatting [2,10]. A history of such sustained pressure should be elicited.

Figure 75.1 shows the most common causes of acute and nonacute lesions. Iatrogenic causes should be considered. These include anesthesia for surgery, leading to immobility and possible positioning issues [9,11,12]; surgery about the hip [13–15], knee [16], or ankle [17]; prolonged imposed bed rest with decreased sensorium due to sepsis or coma [2,18]; intermittent sequential pneumatic compression [19]; acupuncture [20]; and plaster casts [2], braces, sports icing and compression wraps [21], and, ironically, ankle-foot orthoses [5,22]. A history of severe inversion ankle sprain or blunt trauma to the ankle, leg, or fibular head can be helpful in identifying likely pathophysiologic mechanisms.

Stretch injury commonly occurs at the hip region and may be associated with hip surgery (e.g., total hip arthroplasty, especially if the limb is lengthened) [13] or traumatic hip dislocation. The peroneal portion of the sciatic nerve is more susceptible to stretch injuries than the tibial portion because of its lateral position and the shorter distance between the piriformis and the fibular head than between

FIGURE 75.1 Predisposing factors in 103 patients with peroneal mononeuropathy divided between acute onset and nonacute onset. (From Katirji MB, Wilbourn AJ. Common peroneal mononeuropathy: a clinical and electrophysiologic study of 116 lesions. *Neurology* 1988;38:1723-1728.)

the piriformis and the tarsal tunnel (e.g., the sites of relative fixation of these two nerves). Distal peroneal nerve stretch injury can also occur at the point where it passes through the peroneus longus muscle. In addition, peroneal nerve injury is proposed to occur after stroke by equinovarus foot-drop posturing [23].

Symptoms

Peroneal neuropathy typically is manifested with acute foot-drop, but this can sometimes occur insidiously during several days to weeks. The footdrop can be complete or partial, often with increased tripping or falls as the primary complaint. Numbness or dysesthesias frequently occur in the lower lateral leg and dorsum of the foot, although pain is uncommon. When pain is present, it is usually located around the knee and felt as deep and ill-defined [2]. When pain is prominent and neuropathic in character, stretch injury of the peroneal portion of the sciatic nerve should be considered.

Physical Examination

The examination should be guided by a close understanding of the relevant anatomy, with focused study of the elements of each component of the peroneal nerve.

Sensory deficits in the upper lateral leg (Fig. 75.2) suggest a lesion proximal to the fibular head. Testing of foot inversion, to rule out concomitant tibial nerve compromise and therefore sciatic nerve as the likely site of injury, must be performed with the foot passively slightly dorsiflexed for optimal strength testing (often the foot will initially, at rest, be in a plantar flexed position during examination as a result of the existing footdrop) because inversion is normally weak when the foot is relatively plantar flexed [1]. With the long head of the biceps femoris intact, knee flexion strength will test

FIGURE 75.2 Common (blue) and superficial (purple) peroneal nerve branch cutaneous distributions and motor branches. (From Haymaker W, Woodhall B. *Peripheral Nerve Injuries: Principles of Diagnosis*. Philadelphia, WB Saunders, 1953.)

normal despite a compromise to the short head of the biceps femoris strength. Palpation may reveal a lack of tissue tensing where the short head of the biceps femoris should be located. This is, however, challenging to discern and helpful only in the case of acute complete proximal peroneal nerve compromise with relative sparing of the tibial-innervated hamstring muscles. The function and innervation of the long and short heads of the biceps femoris can be more accurately determined electrophysiologically. If both are compromised, knee flexion will be weak, as will plantar flexion and toe flexion, suggesting a sciatic nerve lesion. Hip abduction strength testing has been found helpful in distinguishing peroneal neuropathy from L5 radiculopathy in patients with footdrop [24]. Muscle stretch reflexes will usually be normal unless the sciatic nerve is severely compromised, when the medial hamstring and Achilles reflexes could be reduced or absent.

Sensory deficit or dysesthesia in the lower lateral leg and over most of the dorsum of the foot suggests involvement of the superficial peroneal or this portion of the sciatic nerve (see Fig. 75.2). Eversion weakness is consistent with superficial peroneal nerve compromise. If the superficial peroneal nerve lesion is isolated, then Achilles, quadriceps, and medial hamstring muscle stretch reflexes will be normal.

If eversion is strong but dorsiflexion is very weak, a more focal deep peroneal nerve compromise is suggested. There may be sensory deficits or dysesthesias along the isolated area of the dorsum of the first web space of the foot on the affected side (Fig. 75.3). A combination of deep and

FIGURE 75.3 Deep (blue area) peroneal nerve cutaneous distribution and motor branches. (From Haymaker W, Woodhall B. *Peripheral Nerve Injuries: Principles of Diagnosis*. Philadelphia, WB Saunders, 1953.)

superficial peroneal nerve branch compromise often occurs, usually affecting the deep branch more severely than the superficial branch, especially with lesions at the fibular head.

Functional Limitations

The most common limitation is due to footdrop. This can lead to frequent tripping or falls and altered gait with foot slapping, circumduction, or hip hiking. These gait compensations require more energy per distance for walking and place one at a greater fall risk than if they are corrected by an ankle-foot orthosis. Any task requiring dynamic foot eversion or dorsiflexion muscle activity, such as walking and running or balance activities such as occur during lower extremity dressing, bathing, sports activities, or driving (especially when the right side is affected) [25], can be impaired.

Diagnostic Studies

Electrophysiologic studies are the “gold standard” for diagnosis of suspected peroneal neuropathy [1,26–29]. These studies can help distinguish site and severity of compromise from other possible causes of footdrop (see the section on differential diagnosis) [1,2,26]. This includes both sensory nerve conduction studies of the superficial peroneal nerve and motor nerve conduction studies of the common, deep, and superficial peroneal nerve to the functionally deficient muscles, such as the tibialis anterior or peroneus longus. Although the peroneal motor nerve

is commonly studied to the extensor digitorum brevis for polyneuropathy screening, this is not the targeted muscle to evaluate footdrop, or dorsiflexion weakness, as the tibialis anterior is the more relevant and germane motor conduction study [2,26]. Needle electromyography, especially of the short head of the biceps femoris, can help determine if the lesion is proximal to the fibular head. Additional prognostic and severity data can be obtained by needle study as well as by comparison nerve conduction studies between the involved and uninvolved sides.

If the etiology cannot be determined with reasonable certainty, imaging studies can help identify less common, nontraumatic causes of peroneal neuropathy. These include ganglia [30], nerve tumors (primary nerve sheath, benign or malignant, or metastatic tumors with invasion or compression) [29], hematomas (especially with anticoagulation or bleeding dyscrasias) [2], aneurysms [31], venous thromboses [32,33], and knee osteoarthritis [34,35]. The most common imaging study is magnetic resonance imaging along the course of the nerve [13,36–38], but imaging studies could include plain radiography or ultrasonography, which is becoming more widely available and used [30,39–42].

Differential Diagnosis

- Cerebral lesions, especially midline cortical
- Spinal cord lesions, Brown-Séquard syndrome
- Lumbosacral radiculopathy, especially L5
- Lumbosacral plexopathy
- Compartment syndromes in the leg (especially anterior compartment)
- Acute or subacute polyneuropathy
- Motor neuron disease

Treatment

Initial

Treatment depends on lesion site and prognostic factors found on electrophysiologic studies. If a good prognosis is predicted, watchful waiting is indicated with temporary adaptations and preventive measures to minimize functional impact until complete recovery occurs. Removal of pressure to the involved area is important, and this may require bed rail modifications or protective padding around the knees, especially for sleep. Work or sports activities and clothing that could result in pressure to the involved areas should be assessed and modified to eliminate any unnecessary pressure or padding added to minimize blunt trauma effects. Habitual leg crossers must modify this behavior. With pressure relief, neurapraxic injuries often significantly improve by 6 weeks. If the lesion is more axon stretch, recovery can take much longer, as much as a day for each millimeter that the axon must regrow. Completely denervated muscles need reinnervation by 18 months for recovery; the higher the lesion, the more likely a poor outcome will result for distal muscles. If prognosis is poor, such as with a severe high sciatic nerve injury, longer term adaptations and home preventive programs should be planned, as well as possible surgical considerations, especially in children [43].

If pain is neuropathic in nature (burning, tingling, or associated with hyperpathia), neuropathic pain medications such

as the anticonvulsants or tricyclic antidepressants should be considered. These must be started in low dosage, taken routinely, and slowly titrated up; a steady-state level is needed to help block the new aberrant sodium channels of injured nerves, which is one mechanism by which these medications decrease neuropathic pain. These medications are not used on an as-needed basis like other more typical analgesics. When they are effective, the neuropathic pain medications tend to continue to be effective chronically and are often needed 6 months to 2 years, if not indefinitely [44].

Rehabilitation

Adaptive devices include an ankle-foot orthosis, which can be a simple, fixed-ankle, off-the-shelf model if no other comorbidities exist. This brace helps with footdrop and improves foot clearance during the leg swing-through phase of gait. If the peroneal neuropathy occurs in isolation, then no plantar sensory loss is present, and concerns for contact pressure of skin to orthosis are lessened. If the patient presents with comorbid tibial nerve deficits, custom molding of the ankle-foot orthosis to minimize contact pressures to the skin should be considered. If the prognosis is poor or recovery not forthcoming, the addition of dorsiflexion assist to the ankle-foot orthosis may help restore an even more normal gait than is achievable with a fixed ankle. With significant obesity or edema or in the face of severe polyneuropathy requiring special accommodative shoe wear, a dual upright ankle-foot orthosis may be indicated. The addition of dorsiflexion assist can easily be accomplished by adding springs to the posterior channels of a dual upright ankle-foot orthosis. The addition of dorsiflexion assist may be mandatory if the patient is having difficulty driving and right foot involvement is the cause. Most patients will have a stable and safe gait with an ankle-foot orthosis without additional gait aids, such as walkers, crutches, or canes; but when needed, gait training with any necessary gait aids should be ordered through physical therapy.

Because of the unbalanced weakness of the dorsiflexors, the lesser or unopposed plantar flexors must be actively stretched on a daily basis to prevent contracture development, which can occur in a matter of weeks. Similarly, the inverters may also need to be stretched in a home exercise program if the eversion function has been compromised. Splinting can also assist with contracture prevention and treatment.

As the muscle recovers function, which may occur during a few months if it is due to axonotmetic compression at the fibular head, strengthening can be initiated once manual muscle strength greater than 3/5 (antigravity strength but unable to take any resistance) returns. It is probably not prudent to exercise the newly reinnervated muscle to exhaustion, but moderate strengthening can be well tolerated. Patients may begin household ambulation without their ankle-foot orthoses before going long community distances. Patients should be advised to use their ankle-foot orthoses whenever prolonged walking is anticipated, even when manual muscle testing initially reveals 5/5 strength, because of early fatigue on initial strengthening.

Procedures

Although common peroneal neuropathy at the fibular head is rarely complicated by severe pain, sciatic or more distal

superficial peroneal nerve stretch with axonotmesis can result in neuropathic pain. Medications focused on neuropathic pain are the mainstays of treatment, but additional nerve block is occasionally needed to resolve the associated pain adequately [44].

Surgery

When expected improvement does not occur or imaging studies reveal structures creating possible compromise of the nerve's function, surgical exploration, compression relief, or neurotomy or resection of compromising tumors, synovial cysts or ganglia, or other structures may be needed [45–47]. For poor-prognosis, high sciatic near-complete or complete peroneal lesions, a new technique of transplanting some tibial nerve elements into the denervated tibialis anterior muscle has been successful, especially in children, in restoring function where previous footdrop existed [43]. Tendon transfers have also been used with variable success [45].

Potential Disease Complications

A common complication of peroneal neuropathy is footdrop and its deleterious effects on gait and balance, leading to falls and additional trauma. The sensory impairments place portions of the lateral leg and foot dorsum at risk for pressure ulcers or acute injuries that are not adequately treated because of lack of pain and sensation in those areas. If range of motion of the ankle is not adequately addressed, ankle contractures can result, further impairing gait and ankle-foot orthosis use.

Potential Treatment Complications

Any surgical treatment has the potential for infection, excessive bleeding, anesthetic death, and making the condition worse. Procedures likewise could worsen the condition and are used only when pain is intolerable and recalcitrant to medication interventions. Pain medications are most typically neuropathic pain-focused medications, such as tricyclic antidepressants (e.g., amitriptyline) and anticonvulsants (e.g., gabapentin). These have unique contraindications and side effect profiles. These medications must be initiated at a low dose and built up over time to minimize the occurrence of side effects. They are not used in an as-needed fashion like the more typical analgesics (such as nonsteroidal anti-inflammatory drugs) or opioids. Opioids tend to be less often used because of the chronic and neuropathic nature of most associated pain. Nonsteroidal anti-inflammatory and opioid drugs also have unique side effect profiles. Physical dependence and development of tolerance with opioids must be considered because the neuropathic pain from peroneal nerve lesions is most often a chronic issue.

CHAPTER 76

Posterior Cruciate Ligament Sprain

Farshad Adib, MD
Christine Curtis, MD
Peter Bienkowski, MD
Lyle J. Micheli, MD

Synonym

Posterior cruciate ligament tear

ICD-9 Codes

717.84 Old disruption of posterior cruciate ligament
844.2 Acute posterior cruciate ligament tear

ICD-10 Codes

M23.621 Spontaneous disruption of posterior cruciate ligament of right knee
M23.622 Spontaneous disruption of posterior cruciate ligament of left knee
M23.629 Spontaneous disruption of posterior cruciate ligament of unspecified knee
S83.521 Sprain of posterior cruciate ligament of right knee
S83.522 Sprain of posterior cruciate ligament of left knee
S83.529 Sprain of posterior cruciate ligament of unspecified knee
Add seventh character to category S83 for episode of care (A—initial encounter, D—subsequent encounter, S—sequela)

Definition

Posterior cruciate ligament (PCL) tears represent 5% to 38% of all knee ligament injuries [1,2]. The PCL is an intra-articular but extrasynovial structure that arises from the posterior aspect of the tibial plateau (about 1 cm distal to the joint line),

crosses (“cruciate”) behind the anterior cruciate ligament (ACL), and inserts into the lateral portion of the medial femoral condyle (Fig. 76.1). The main function of the PCL is to resist posterior displacement of the tibia on the femur. It also acts as a secondary restraint to external tibial rotation. The PCL also has some restraint against varus and valgus forces. The larger and stronger anterolateral bundle is tight in flexion, whereas the posteromedial bundle is tight in extension. The anterior meniscomfemoral ligament (Humphry) and posterior meniscomfemoral ligament (Wrisberg) make a Y-shaped sling around the PCL [3]. The average distance between the center of the femoral attachments of anterolateral and posteromedial bundles is 12.1 ± 1.3 mm; this distance on the tibial side is 8.9 ± 1.2 mm [4].

Together with the ACL, the PCL functions in the “screw-home” mechanism of the knee by which the tibia glides to its exact position at terminal knee extension. In general, PCL tears occur in a flexed knee when the tibia is displaced posteriorly. This can occur in a motor vehicle accident (dashboard injury) or during a fall on a flexed knee with the foot in plantar flexion. The PCL may also rupture from hyperextension and rotation on a planted foot or on forced hyperflexion. PCL injuries may occur in isolation, but they generally occur with other injuries (e.g., ACL tear, collateral ligament tear, and meniscal injuries).

In a chronic PCL-deficient knee, an increase of force on the medial and patellofemoral compartments might lead to development of early degenerative arthritis [5]. In contrast to ACL injuries, most series of PCL injuries have reported a higher incidence of injury to men [6]. Fewer studies have been done about PCL injuries in comparison to ACL injuries.

Symptoms

It is important to obtain information about the nature of the injury. Typically, patients report that they have fallen on a flexed knee or have sustained a blow to the anterior knee when it was flexed (e.g., on the dashboard of a car). Rarely, patients may recall feeling or hearing a “pop” at the time of injury (more common in ACL tear). Patients may

FIGURE 76.1 Anterior and posterior cruciate ligament structures.

have pain in the posterior aspect of the knee in the acute cases or along the medial or patellofemoral region in the chronic cases.

Patients may report instability, stiffness, and an inability to bear weight and to walk. Swelling can range from insignificant to very swollen.

Physical Examination

In an acute injury, there may be contusion of the anterior tibia, and popliteal ecchymosis may be present. Swelling and effusion will vary and may not be present at all. Limb alignment, gait pattern, and range of motion should be evaluated. See [Table 76.1](#) for the general classifications of PCL injuries. It has been shown that a grade III on posterior drawer testing and posterior tibial translation on stress radiography of more than 10mm correlate with the presence of a posterolateral corner injury in addition to a complete disruption of the PCL [7].

It is essential during the examination of the knee to evaluate all knee ligaments thoroughly to identify combined ligamentous injuries. The goal of PCL evaluation is to identify posterior subluxation of the tibia, which occurs with PCL insufficiency.

The “gold standard” of PCL examination is the posterior drawer test ([Fig. 76.2](#)). During this test, the knee is flexed at 90 degrees with the hip held at 45 degrees of flexion. It is essential to appreciate a normal 1-cm step-off of the medial tibial plateau anterior to the medial femoral condyle. The absence of the step-off should alert the clinician to a possibility of PCL injury. Posterior pressure is applied to the tibia while the amount of displacement of the medial tibial step-off and the quality of the endpoint in comparison with

Table 76.1 Classification of Posterior Cruciate Ligament Injuries

Grade	Definition	Laxity (mm)
I	PCL partially torn	<5
II	PCL partially torn	5-9
III	PCL completely torn	>10
IVa	PCL and LCL, posterolateral injury	>12
IVb	PCL and MCL, posteromedial injury	>12
IVc	PCL and ACL injury	>15

Note: grades I to III are isolated injuries; grade IV is a combined injury.

ACL, anterior cruciate ligament; LCL, lateral collateral ligament; MCL, medial collateral ligament; PCL, posterior cruciate ligament.

Posterior cruciate ligament injuries of the knee joint. *Sports Med* 1999;28:429-441.

FIGURE 76.2 Posterior drawer test.

the contralateral knee are noted. Posterolateral instability may be evaluated by the posterior drawer test with the foot externally rotated 15 degrees. Similarly, posteromedial instability is assessed by the posterior drawer test with the foot internally rotated 15 degrees.

The posterior Lachman test involves positioning of the knee at 30 degrees of flexion with posterior pressure applied to the proximal tibia ([Fig. 76.3](#)). The extent of displacement and the quality of the endpoint are evaluated and compared with the contralateral knee.

The posterior sag test is performed with the patient supine with the hips and knees at 90 degrees of flexion ([Fig. 76.4](#)). The clinician grasps both heels and inspects for posterior tibial translation consistent with an insufficient PCL.

The reverse pivot shift includes a valgus-loaded, externally rotated knee moved from 90 degrees of flexion to full extension ([Fig. 76.5](#)). A positive test result is indicated by a pivot shift felt at 20 to 30 degrees when the posteriorly subluxated tibia is reduced.

The dynamic posterior shift test is implemented by extending the knee from 90 degrees of flexion to full extension with 90 degrees of hip flexion. A positive result is indicated if the tibia is reduced with a “clunk” near full extension.

The quadriceps active test is achieved with the knee flexed at 60 degrees while the foot is secured by the clinician.

FIGURE 76.3 Correct position for posterior Lachman test.

FIGURE 76.4 Posterior tibial sag test.

The patient attempts to extend the knee statically. PCL insufficiency is demonstrated by anterior tibial translation from a subluxated position.

A careful neurovascular examination should be performed to rule out any injury to the popliteal artery and tibial and peroneal nerves. Some weakness of muscle may be detected because of pain or inactivity. Physical examination under anesthesia is a critical step before reconstruction.

Functional Limitations

Functional limitations of PCL tears may include difficulty with walking and a decrease in the level of functioning because of pain as well as apprehension of instability. Athletes may be unable to complete cutting movements. However,

FIGURE 76.5 Reverse pivot shift test. **A**, The knee is flexed to 90 degrees. A valgus, external rotation force is applied to the knee. **B**, The knee is extended while the valgus, external rotation is maintained. **C**, Near full extension, the lateral tibia shifts forward, reducing the knee and confirming PCL deficiency.

PCL injury is often less debilitating than ACL injury, and many athletes are still able to participate effectively in running sports. Return to sport after treatment of PCL injury is common, but in the majority of cases, development of degenerative changes is inevitable [8].

Diagnostic Studies

Diagnostic testing is useful as an adjunct to the clinical examination. The KT-1000 arthrometer is highly specific in the detection of high-grade (grade II, grade III) PCL tears [9]. Stress radiographs may document the extent of posterior instability but are rarely obtained in settings where magnetic resonance imaging is readily available. After an acute injury, plain radiographs must be performed to rule out fractures, including PCL avulsions (the tunnel view is best to visualize this). Magnetic resonance imaging assessment is highly specific and sensitive in assessment of PCL injuries, particularly when newer fat suppression and “fast spin” techniques are used [10–12]. Finally, diagnostic arthroscopy allows direct visualization of the PCL.

Differential Diagnosis

- Anterior cruciate ligament tear
- Collateral ligament tear
- Meniscal tear
- Osteochondral fracture
- Patellar tendon rupture
- Patellofemoral dislocation
- Tibial plateau fracture

Treatment

Initial

Initial treatment consists of *protection, rest, ice, compression, and elevation (PRICE)*, crutches, an extension brace, and short-term nonsteroidal anti-inflammatory drugs. Analgesics may be used to control pain if this is an issue. Currently, nonoperative treatment is advocated for those with isolated PCL injuries with mild (grade I or grade II) laxity [9]. Some recommend conservative treatment for acute, isolated PCL injury as well as for chronic, isolated, asymptomatic PCL injury when it is newly diagnosed with no history of prior rehabilitation [13]. Subjective scores of patients with acute, isolated PCL injuries were independent of grade of PCL laxity, and mean scores did not decrease with time from injury [14].

Rehabilitation

Nonoperative rehabilitation begins after the signs and symptoms of acute injury have subsided (7 to 10 days). Range of motion and progressive resistance exercise for the quadriceps is initiated while posterior tibial sag is prevented. The use of a PCL functional brace has not been proved to be effective, although some patients may find it useful [15]. After acute symptoms have subsided, or immediately in dealing with a chronic tear, daily stationary bicycle exercises can be initiated. After 3 months, closed chain exercises are started, with the exception of isolated hamstring strengthening, which is done later in the course [16].

Postoperative PCL rehabilitation includes initial bracing in full extension to prevent posterior tibial translation. Continuous passive motion, straight-leg raising, and quadriceps static exercises are initiated immediately after surgery.

The day after surgery, partial weight bearing with crutches is initiated as tolerated. In the early phase of rehabilitation, gravity-assisted flexion exercises to 90 degrees and closed chain exercises emphasizing quadriceps muscle strengthening are pursued. The progression to more than 90 degrees of flexion is delayed until 6 weeks after surgery. Rehabilitation after PCL reconstruction is more conservative than after ACL reconstruction.

Two studies by Italian investigators have documented the frequent clinical observation that the PCL, in contrast to the ACL, can undergo in situ healing of partial lesions, with improved stability and function [17–19]. This has been attributed to the capsular contiguity of the ligament, with better opportunity for revascularization than in the ACL [1]. It is thus imperative that the ligament be protected from undue stress during the rehabilitative phase of treatment. Intact meniscomfemoral ligaments may support the injured PCL during the healing phase. This scaffold effect of meniscomfemoral ligaments could be another reason for the healing potential of PCL injuries. At 9 to 12 months after surgical intervention, the patient with full range of motion, equal strength compared with the contralateral leg, and a stable knee is allowed to return to full activity.

Procedures

Arthrocentesis is performed for painful effusions (hemarthrosis). As mentioned earlier, KT-1000 arthrometer testing is done for diagnostic purposes and to document the degree of instability [9].

Surgery

Surgical intervention is advocated for patients with bone avulsion fractures, combined ligament injuries, and chronic symptomatic PCL laxity, particularly if this interferes with athletic participation in elite athletes [15]. In a high percentage of cases, athletic participation is still possible with PCL insufficiency [6]. Management includes immobilization in extension with a Velcro knee immobilizer and avoidance of hamstring exercise. It is important to keep in mind that grade III PCL injury almost always is associated with the posterolateral corner injury, which must be addressed at the time of PCL reconstruction to obtain a good clinical result.

Bone avulsions are best treated with anatomic repair, either by open technique with screws or by an arthroscopic method with anchor sutures [20]. Various surgical techniques have been developed for the reconstruction of the PCL. Controversy exists as to the most effective procedure [16]. The aim of surgery is to replace the PCL with a graft inserted into a tunnel drilled through the tibia and femur. Allograft or autograft tissue is most commonly used. Donor sites include the patellar tendon, the hamstring tendons, and, rarely, the quadriceps tendon [21]. Achilles tendon allograft is also useful. A mixed graft consisting of a hamstring (semitendinosus and gracilis) autograft plus tibialis anterior allograft tendon has been used with good results [22]. PCL reconstruction with artificial ligament is an alternative treatment option [23]. PCL reconstruction is performed arthroscopically, arthroscopically assisted, or open [13]. In the presence of significant bone malalignment, it should be addressed simultaneously or as

the first step before the reconstruction. Proximal tibial slope should be considered in treating combined PCL and posterolateral corner injuries of the knee. It has been shown that increasing posterior tibial slope may improve sagittal stability in the PCL- and posterolateral corner-deficient knee [24].

Potential Disease Complications

Potential disease complications include pain, limitation of function and activity, and onset of degenerative arthritis. Patients with isolated PCL tears tend to fare better than do patients with combined ligamentous injuries [25]. Studies suggest that nonoperatively treated PCL injuries allow many athletes to return to their sport independent of level of laxity [25]. However, late degenerative arthritis has been reported as a consequence of PCL instability [26].

Potential Treatment Complications

Treatment complications include the well-known side effects of nonsteroidal anti-inflammatory drugs. Prolonged bracing or immobilization can lead to significant muscle weakness and atrophy. The risks of surgery, although uncommon, are also well known. These include the risks of anesthesia. In addition, bleeding is controlled with a tourniquet and surgical hemostasis. Infection is limited with diligent sterile technique as well as with antibiotics. Damage to nerve and vascular structures, the popliteal vessels in particular, is a slight risk. Postoperative laxity of the PCL graft may occur. The theoretical risk of disease transmission with the use of allograft tissues is extremely low.

Definition

The quadriceps tendon is located at the insertion of the quadriceps muscle into the patella and functions as part of the knee extensor mechanism. Quadriceps tendinitis (or, as named in the more recent literature, tendinosis or tendinopathy) is an overuse syndrome characterized by repetitive overloading of the quadriceps tendon. The common mechanism of injury is microtrauma, in which the basal ability of the tissue to repair itself is outpaced by the repetition of insult [1]. Quadriceps tendinopathy often occurs in athletes participating in running and jumping sports as well as in persons who perform frequent kneeling, squatting, and stair climbing [2]. The superior strength, mechanical advantage, and better vascularity of the quadriceps tendon make quadriceps tendinopathy much less frequent than patellar tendinopathy [3].

Symptoms

Patients usually report an insidious onset of knee pain and may note painful clicking. Their chief complaint is usually “knee pain.” A burning sensation at the bone-tendon junction may be experienced [4]. The pain is aggravated by activity that challenges the extensor mechanism, including bending, stair climbing, running, and jumping. Reports of severe weakness, an inability to extend the knee, or the report of acute trauma with a “pop” should alert the clinician to the possibility of a quadriceps tendon partial or complete rupture. On occasion, a single episode of overload may elicit symptoms.

Physical Examination

On examination of the knee, point tenderness is localized along the superior pole of the patella and the quadriceps

tendon. Quadriceps tendon pain may be elicited with extreme knee flexion and by resisted knee extension. The clinician should also be on the lookout for a palpable defect, suggesting partial rupture of the quadriceps tendon. Neurologic examination findings should be normal, with the possible exception of strength testing, which may be limited by pain or partial tendon rupture. Ligamentous examination of the knee is normal unless there is an internal derangement of the knee associated with trauma.

Functional Limitations

Quadriceps tendinopathy may interfere with activities of daily living. Pain is usually felt with stair climbing, kneeling, and rising from a chair. Athletes may be unable to participate in running and jumping activities.

Diagnostic Studies

Quadriceps tendinopathy is a clinical diagnosis, and diagnostic investigations are not generally necessary. If a partial tear of the quadriceps tendon is suspected but not apparent clinically, magnetic resonance imaging may be of assistance in confirming the diagnosis. Ultrasonography and Doppler study have also been found to be helpful [5].

Differential Diagnosis

Patellar tendinitis
Patellar fracture
Patellofemoral syndrome
Prepatellar bursitis
Apophysitis
Anterior fat pad syndrome
Chondromalacia patellae
Osteochondritis dissecans
Plica
Quadriceps tendon rupture
Quadriceps strain
Quadriceps contusion
Quadriceps tear

Treatment

Initial

Initial treatment includes rest from aggravating activities. Activity modification should include protection from eccentric or high-load knee extension (e.g., going up and down stairs, bending, jumping). Proper warm-up and stretching should be conducted before activity. Also, the application of ice to the injured area for 20 minutes, two or three times daily and before and after athletics, can be useful. Nonsteroidal anti-inflammatory drugs may be used for pain and inflammation. In some instances, knee immobilizers are used but may promote weakness and disuse atrophy.

Rehabilitation

The main rehabilitation modality includes muscle strengthening and stretching. All muscle strengthening exercises are conducted in the pain-free range. Static exercises may

be used to minimize compressive forces across the patellofemoral joint [2]. Eccentric strengthening exercises may be useful [6]. Therapeutic modalities including ultrasound, phonophoresis, and iontophoresis may be used [2]. The use of icing immediately after activity or work has been advocated [7]. A general conditioning program is recommended.

Procedures

Local corticosteroid injections are not typically done because of the risk of tendon rupture, but they may be necessary in some cases unresponsive to treatment. Care should be taken to inject circumferential to the tendon and not in the tendon itself.

Surgery

Quadriceps tendinopathy is mostly managed nonoperatively. Surgical intervention may be necessary in rare cases of partial rupture. Tendocalcinosis may reflect a chronic partial tear [8]. If partial tendon rupture is suspected, surgical consultation is advised.

Potential Disease Complications

Functional deterioration with the development of chronic symptoms may occur. A high level of functioning in patients with quadriceps tendinopathy is usually regained and maintained [2]. In rare cases of progressive microtrauma to the injured area, rupture of tendon may result.

Potential Treatment Complications

The complications related to the use of nonsteroidal anti-inflammatory drugs include the development of gastritis as well as renal and hepatic involvement. Corticosteroid injection may predispose the tendon to rupture. Repeated injections of corticosteroids may increase the risk for mucoid degeneration, fibrinoid necrosis, mineralization, fibroblastic degeneration, and capillary proliferation within the tendon [9].

Definition

“Shin splints” is best thought of as a clinical syndrome defined in terms of pain and discomfort in the anterior portion of the leg from repetitive activity on hard surfaces or from forcible, excessive use of the foot flexors. The diagnosis should be limited to musculoskeletal inflammations, excluding stress fractures, diet-related diseases [1], and ischemic disorders [2], although it may coexist with such disorders.

Shin splints most commonly occur in athletes who have sudden increases or changes in their training activity. This disorder occurs in runners and in athletes who participate in high-impact court or field sports as well as in gymnasts and particularly ballet dancers, alone or in conjunction

with other overuse syndromes [3], but it has also been well documented and studied in military personnel [4–6]. The etiology of shin splints is not clearly defined, but it is likely to be multifactorial with biomechanical abnormalities of the foot and ankle, poor footwear and shock absorption, hard playing surfaces, and training errors. Other contributing factors may include weakness of anterior and posterior compartment musculature, inadequate warm-up, leg length discrepancy, tibial torsion, excessive femoral anteversion, and increased Q angle [7,8], as is seen in women.

One prospective study [6] in military cadets looked at seven anatomic variables and identified greater internal and external hip range of motion and lower mean calf girth to be associated with a higher incidence of exertional medial tibial pain in men. It also showed a high rate of injury among women, but no intrinsic factor was specifically identified. Nutritional and endocrine factors are more likely to play an etiologic role in stress reactions. In school-age athletes and adults who participate in seasonal sports, shin splints can occur when they resume their sport or start a new land-based sport (e.g., high-school or college athletes who go from playing basketball to cross-country or track).

It is important for the clinician to differentiate shin splints, a fairly benign condition, from acute compartment syndrome (a potential emergency) and from the different types of stress fractures that can occur in this region. The anterior lower leg is especially predisposed to compartment syndrome because of its high vulnerability to injury and its relatively limited compartment compliance [9]. It is most common to study these diagnoses together because many may coexist and symptoms overlap. Further discussion of these other diagnoses may be found in their respective chapters. Tibial periostitis has been described as an initial manifestation of polyarteritis nodosa [10]. Primary adamantinoma [11], a rare low-grade primary bone tumor, and hydatid bone disease [12] have also been reported in this region.

Symptoms

Patients presenting with shin splints usually complain of a dull and aching pain near the junction of the mid and distal thirds of the posteromedial or anterior tibia (Fig. 78.1). Clinicians should be aware of the wide differential diagnosis of pain in this region; not all anterior tibial pains are shin splints. Symptoms are commonly bilateral, occur with exercise, and are relieved with rest [13]. Initially the pain may

FIGURE 78.1 Repetitive microtrauma and overuse in running lead to soft tissue and even bone breakdown, a process commonly called shin splints. Muscle overpull can lead to periostitis, strain, or trabecular breakdown. The area approximately 13 cm proximal to the tip of the medial malleolus along the posterior tibial cortex appears to be maximally at risk.

ease with continued running and recur after prolonged activity. Those with more severe shin splints may have persistent pain with normal walking, with activities of daily living, or at rest.

Physical Examination

Physical examination typically reveals generalized tenderness along the medial tibia. Mild swelling may be present. Resisted plantar flexion, toe flexion, or toe raises may aggravate symptoms, and pain-inhibitory weakness may be evident. Striking a 128-Hz tuning fork and placing it on the tibia may reproduce the pain associated with stress fractures. Patients with stress fractures will usually have point

tenderness over the bone at the site of stress fracture. Lower extremity idiopathic osteonecrosis is most common in the fifth decade of life at the medial tibial plateau [14], whereas those with shin splints will have more widespread tenderness to palpation that is more distal than these other pathologic processes. However, longitudinal tibial stress reactions may share a common anatomic pain distribution, and one study [15] showed tibial stress reactions in this same distal-third region.

The lower extremity examination focuses on static and dynamic components of the kinetic chain to uncover signs of coexisting lower extremity issues that may be contributing factors. These include forefoot pronation, pes cavus, pes planus, and excessive heel valgus or varus. Comparatively tight or weak lower extremity muscle groups should be noted for later rehabilitation goals. In particular, relative ankle plantar flexion, dorsiflexion, inversion, and eversion strength should be examined. Careful review of systems should be negative for fever, chills, night sweats, unintentional weight loss, and loss of bowel or bladder control. The neurologic portion of the examination, including sensation and muscle stretch reflexes, should be normal.

Functional Limitations

In early stages of shin splints, activity limitations occur most often during running or participation in ballistic activities. When symptoms are more severe, they may occur with walking or at rest, thus causing further functional limitations. Athletes may be unable to participate in their sport, and attempts to cross-train into other sports may result in worsening of symptoms.

Diagnostic Studies

Plain radiographs are typically normal early in the disease process but may be of use in ruling out more ominous disease, especially if symptoms are manifested unilaterally. Later, there may be evidence of periosteal thickening. Radionuclide bone scanning helps differentiate shin splints from stress fracture. Diffuse radioisotopic uptake along the medial or posteromedial tibia on the delayed phase is the pattern usually seen with shin splints. A focal defined area of uptake in all phases is more consistent with a stress fracture [16]. Fat-suppressed magnetic resonance imaging may also be useful for discrimination between stress fracture and shin splints before plain radiography shows detectable periosteal reaction [17]. Exertional compartment syndrome is uncommon, but if clinical suspicion is high, compartment pressure measurements must be done to rule it out. Magnetic resonance imaging of the lumbar spine may be indicated if lumbar radiculopathy is in the differential diagnosis or lumbar spinal stenosis is suspected in older athletes or younger athletes with a congenitally narrow spinal canal. Electrodiagnostic studies should be essentially normal, but membrane irritability manifested as positive sharp waves or fibrillations may be seen in any inflamed muscle. Nerve conductions should be normal in the absence of any concomitant nerve entrapment as may be seen in compartment syndrome.

Differential Diagnosis

Stress fracture
Chronic exertional compartment syndrome
Tendinitis
Muscle strain
Muscle herniation
Vascular and muscular abnormalities
Longitudinal tibial fatigue fracture
Hematoma
Primary muscle disease
Peroneal nerve entrapment
Fascial defect
Deep venous thrombosis
Sarcoma or osteosarcoma
Hydatid bone disease

Treatment

Initial

As with many overuse syndromes, relative rest—that is, participation only in those activities that can be done without pain—is the key to initial management. If reducing mileage, court time, or studio time or just reducing intensity allows the athlete to remain pain free, continuation of the activity may be acceptable. In general, however, even in mild cases, the athlete should avoid repetitive lower extremity stress for at least 1 to 2 weeks. In more serious cases, athletes may need to stop running entirely for a longer time. If walking is painful, crutches are indicated. A variety of commercially available off-the-shelf braces may decrease pain associated with weight bearing. Wearing of an elastic compression bandage may prevent additional swelling when compartment syndrome has been ruled out as compression may worsen vascular symptoms.

Stretching and ice or ice massage to the involved areas can be helpful. Nonsteroidal anti-inflammatory drugs can reduce inflammation and help manage pain. Analgesics can be taken for pain, but caution should be used to not enable further overtraining. Whirlpool, phonophoresis, iontophoresis, and therapeutic ultrasound are traditionally attempted and may have a role in symptomatic management or inflammatory phase reduction. Electrical stimulation should probably be considered contraindicated in this diagnosis, in which the pathoetiology points to excessive muscle contraction and a reactive periostitis in the first place.

In addressing malalignments of the lower extremities, orthoses, such as longitudinal arch supports with or without a medial heel wedge, may be indicated in select patients. Although a review of the literature fails to yield any objective evidence for the widespread use of any of these interventions, the most encouraging evidence seems to be for the use of shock-absorbing insoles [4,18]. Custom orthotic inserts, in one study of healthy female runners, have been shown to decrease rearfoot eversion angle and velocity and internal inversion moment as well as to decrease ankle dynamics in the frontal and sagittal planes. Whereas the particular relevance to shin splints is

unclear, the ability to affect these measurements seems promising [19].

Rehabilitation

In individuals who continue to have pain despite initial conservative treatment, physical therapy may be indicated to decrease pain and further educate the patient about the disorder. Although pathophysiologically distinct from chronic exertional compartment syndrome, shin splints were once thought to be a form of chronic exertional compartment syndrome and vice versa [20], and the two entities are seldom discussed outside the context of each other. Ice, passive modalities (except electrical stimulation), and nonsteroidal anti-inflammatory drugs before exercise may help in enabling the rehabilitation program.

Once the symptoms have diminished, the rehabilitation program focuses on improving muscle strength, flexibility, and endurance and preventing recurrence of injury [21]. “Writing” the alphabet with the great toe moves the ankle through full range of motion in all planes and may be started early.

The primary muscles thought to be involved in shin splints are the flexor digitorum longus and the soleus. Others have implicated the tibialis posterior, but its attachment is more posterior than the area of typical shin splint symptoms, and it actually attaches to the interosseous membrane more than to the medial tibia [22]. The deep crural fascia also attaches to the posteromedial tibia. Long-term rehabilitation for shin splints involves improvement of the flexibility, strength, and endurance of the involved muscles and avoidance of contributing factors. Anterior compartment stretching exercises, Achilles tendon stretching, and overall lower extremity flexibility exercises are important. Eccentric strengthening of antagonistic muscle groups is also useful. Pain can be a guide in the advancement of the rehabilitation program.

Athletes should have full range of motion that is symmetric to the uninvolved side and have nearly full strength before returning to their prior activity or to competition. Plyometrics should be avoided until a high level of strength, endurance, and flexibility has been attained. Cardiovascular fitness should be maintained if possible through lower impact activities, such as stationary biking, swimming, or water running. Return to previous activity level should be a gradual process, individualized, and based on the athlete’s response to increasing intensity of training. Proper footwear for the sport is thought to be essential. Running shoes lose more than 60% of their shock absorption after 250 miles of use [7]. Orthotic devices are often necessary in those individuals with foot abnormalities such as pes planus. More specifically, custom orthotics or shoe inserts can help align and stabilize the foot and ankle, taking stress off the lower leg. A plyometric program of strengthening and conditioning has been suggested as early as the third phase of rehabilitation [23], but return to sport outcomes have not been reported.

Procedures

There is no proven benefit noted in the literature to support any injection-based procedure, such as local exogenous

glucocorticoid injection. Limited empirical opinions exist on a role for sclerotherapeutic solutions. Great care must be taken in ensuring the correct diagnosis, as potentially disastrous results may occur in dealing with a coexistent compartment syndrome. Theoretically, a palliative role may exist for either in chronic recalcitrant cases with functional decline. Compartment pressure measurement has no absolute contraindications and can be performed with relative simplicity [24]. Avoidance of areas with overlying cellulitis is recommended. The procedure itself carries some risk of infection, but this can usually be avoided with appropriate technical practices.

Surgery

Surgery is rarely indicated but involves a posteromedial fasciotomy with release of the fascial bridge of the medial soleus and the fascia of the deep posterior compartment, with periosteal cauterization [16]. Surgery is effective in relieving pain, but it frequently leaves the patient with persistent strength deficits, and full return to sports is not always achieved [25].

Potential Disease Complications

If shin splints are not treated and biomechanical malalignments are not addressed, stress fractures and potentially true fractures may occur. This would result in further morbidity and more time lost from the desired physical activity as well as potential function decline. Any chronic tendinopathy can theoretically lead to weakening of the tendon and subsequent rupture [26].

Potential Treatment Complications

Complications involving the gastrointestinal and renal systems may result from treatment with nonsteroidal anti-inflammatory drugs. Fasciotomy may result in residual weakness. Overly aggressive rehabilitation or rehabilitation of the incorrect diagnosis may progress the injury, cause secondary injury, or delay diagnosis of more ominous disease. The author has experience with a case of severe reflex sympathetic dystrophy and peripheral nerve injury after sclerotherapy.

Definition

Stress fractures are complete or partial bone fractures caused by the accumulation of microtrauma [1]. Normal bone accommodates to stress through ongoing remodeling. If this remodeling system does not keep pace with the force applied, stress reaction (microfractures) and, finally, stress fracture can result. Stress fracture is the end result of a continuum of biologic responses to stress placed on bone. Adolescent, young adult, and premenopausal women athletes have a higher incidence of stress injuries to bone than men do [2,3]. Stress fractures in juveniles are rare [4]. Both extrinsic and intrinsic factors have been implicated in this imbalance between bone resorption and bone deposition [5]. Malalignment and poor flexibility of the lower extremities (intrinsic factors) and inadequate footwear, changes in training surface, and increases in training intensity and duration without an adequate ramp-up period (extrinsic factors) can lead to stress fractures [6].

Stress fractures in athletes vary by sports and are most common in the lower extremities [2,7]. The most common sites are the tibia, metatarsals, and fibula, and they affect most commonly runners and dancers. The fracture site is the area of greatest stress, such as the origin of lower leg muscles along the medial tibia [8]. A narrower mediolateral tibial width was a risk factor for femoral, tibial, and foot stress fractures in a study of military recruits [9]. Studies of female runners demonstrated greater loading rates in those with history of tibial stress fractures compared with those without injury [10,11]. In contrast, in comparison of runners with and without history of tibial stress fracture, no difference in ground reaction forces, bone density, or tibial bone geometric parameters was found between groups [12].

Military recruits have been extensively studied in regard to lower extremity stress fractures. In a study of 179 Finnish military recruits aged 18 to 20 years, tall height, poor physical conditioning, low hip bone mineral content and density, and high serum parathyroid hormone level were risk factors for stress fractures [13]. The authors postulated that given the poor vitamin D status, intervention studies of vitamin D supplementation to lower serum parathyroid hormone levels and possibly to reduce the incidence of stress fractures are warranted. Prospective studies of vitamin D and calcium in stress fracture prevention, one in female young athletes and the second in female military recruits, were the focus of a

recent review paper. A longitudinal study of female athletes aged 18 to 26 years showed that greater baseline intakes of dietary calcium, dairy products, and milk were linked to significant reductions in fracture incidence; fracture risk decreased by 62% per additional cup of skim milk consumed per day, and women who consumed less than 800 mg of calcium per day had nearly six times the stress fracture rate of women who consumed more than 1500 mg of calcium and more than double the rate for women who consumed between 800 and 1500 mg [14]. The second study of female military recruits who were prescribed an 8-week trial of supplementation with 2000 mg of calcium and 800 IU of vitamin D demonstrated a statistically significant 20% reduction in fracture injuries compared with women given a placebo [14]. The study concluded that evaluation of age-appropriate dietary guidelines for calcium and vitamin D levels is needed to promote bone health, to reduce the risk of stress fracture injury in the young athlete, and to achieve peak bone density that will promote lifelong bone health [14].

A database of systematic reviews, including 13 randomized prevention trials, concluded that shock-absorbing insert use in footwear probably reduces the incidence of stress fractures in military personnel [15]. There was insufficient evidence to determine the best design of such inserts.

Stress fractures may be related to abnormalities of the bone, such as in female athletes with low bone density due to exercise-induced menstrual abnormalities [16–19]. Premature osteoporosis leads to an increased risk for stress fractures. One study looked at premenopausal women runners and collegiate athletes and concluded that those with absent or irregular menses were at increased risk for musculoskeletal injuries while engaged in active training [17]. Muscle deficits in the gastrocnemius-soleus complex in jumping athletes have also been implicated in causing tibial stress fractures. Bone injury may be a secondary event after a primary failure of muscle function [20].

Recent literature review of the influence of sports participation on bone health in the young athlete concluded that high-impact and weight-bearing activities enhance bone density, particularly in anatomic locations directly loaded by those sports [21]. It also showed that participation in sports during the age range in which growth and skeletal maturity occur may result in a higher peak bone density [21]; in particular, athletes aged 10 to 30 years who participate in impact sports (particularly high-impact or odd-impact sports) may enjoy enhanced bone density and improvements in bone geometry. Nonimpact sports such as cycling and swimming are not associated with improvements in bone health, and prolonged participation in endurance sports, including long-distance running and cycling, may be associated with decreased peak bone density [21].

During the last few years, researchers have shown a link between stress fractures and long-term bisphosphonate use. Bisphosphonate medications are indicated for patients with postmenopausal osteoporosis, and it has been shown that bisphosphonate use improves bone mineral density, prevents bone loss, and reduces the number of fractures [22,23]. Bisphosphonates inhibit osteoclastic bone resorption, and therefore bone turnover, by inducing osteoclast apoptosis.

The combined and coordinated action of resorbing damaged bone and laying down new bone is fundamental to the process of bone remodeling [23]. If this coupling is impaired, the microdamage that occurs under physiologic conditions that normally is repaired may accumulate, resulting in a major reduction in the energy required to cause fracture [23]. These fractures are low-energy injuries and have characteristic findings observed on femoral radiographs: a transverse fracture line originating from the lateral tension side of the cortex and lateral cortical thickening adjacent to the fracture [23,24]. In addition, prodromal thigh pain from the insufficiency changes may be present. The subsequent minimal trauma that often is required to complete the fracture is characteristic, with patients often sustaining a spontaneous nontraumatic fracture during activities of daily living [23].

Individuals who are nonambulatory or have limited ambulation due to disability represent another population with abnormal bone and premature osteoporosis. In stroke patients, there is significant bone loss on the paretic side, which is greatest in those patients with the most severe functional deficits [25]. Spinal cord injury may not only cause bone loss but also alter bone structure and microstructure [26]. Practitioners caring for individuals with limited mobility should consider stress fracture in the differential diagnosis of overuse injuries.

Symptoms

Patients may report an increase in training or activity level or a change in training conditions preceding the onset of symptoms. Because of pain in the affected region of the bone, patients may seek medical attention during the microfracture or stress reaction phase of injury. Should they forego relative rest (avoidance of the pain-provoking activity), they can progress to stress fracture or even complete fracture. The pain will gradually increase with activity and may occur with less intense exercise, such as walking, or even at rest. In general, however, the pain will improve with rest. The pain can lead to a decline in performance. The individual may also note swelling in the affected region of the bone. Symptoms of paresthesias and numbness should alert the clinician to consider an alternative diagnosis.

Physical Examination

On physical examination, the clinician will find an area of exquisite, well-localized tenderness, warmth, and edema over the affected region of the bone. Ecchymosis along the plantar aspect may be present with foot involvement. Percussion of the nearby region can cause pain. Placement of a vibrating tuning fork over the fracture site intensifies the pain [27]. In the tibia, stress fractures primarily occur along the medial border; the frequency, in order, is upper, lower, and mid shaft. In the fibula, they usually occur one handbreadth proximal to the lateral malleolus [5]. Tarsal or metatarsal stress fractures are manifested with localized foot tenderness. Weight-bearing activity, such as a one-legged hop test, can provoke the pain by increasing the ground reaction forces. For a presumed femoral stress fracture, the clinician can provoke pain by applying a downward force on the distal femur while the affected individual is

FIGURE 79.1 Physical examination technique to evaluate for femoral stress fracture. The examiner applies a downward pressure on the distal femur, using the examination table as a fulcrum, to increase the force across the fracture site. A positive test result reproduces the individual's pain.

seated with the distal femur extending beyond the edge of the seat (Fig. 79.1).

The physical examination must include an examination of the lumbar spine and lower limbs to evaluate for any anatomic malalignment or biomechanical abnormalities. For instance, an individual with rigid supinated feet or weak foot intrinsic muscles may transmit more ground reaction forces to the tibia. On physical examination, one can identify problems that must be addressed in treatment planning.

Strength should be normal but occasionally limited by pain. Sensation and muscle stretch reflexes should also be normal.

Functional Limitations

Recreational and athletic activities requiring weight bearing through the affected lower limb may be limited by pain. For instance, running results in the transmission of increased ground reaction forces through the leg. These forces can increase if one runs on a concrete surface versus an all-weather track. In acute cases, ambulation can be painful.

Diagnostic Studies

Plain films may take as long as 6 weeks to demonstrate fracture, and films are initially normal in up to two thirds of patients [28]. Technetium Tc 99m diphosphonate bone scanning will yield the earliest confirmatory data for stress fractures, demonstrating a "hot spot" 1 to 4 days after

FIGURE 79.2 Femoral stress fracture on the compression side of the right femoral neck in a 35-year-old female marathon runner demonstrated on T1 (A) and STIR (B) coronal magnetic resonance images. (Images courtesy David A. Turner, MD, Chairman, Department of Radiology, Rush University Medical Center, Chicago.)

fracture [18]. The fracture site may not return to normal on a bone scan for 5 months or longer, so it is not clinically useful to assess recovery. Computed tomography is necessary to differentiate stress fractures of the sacrum and the tarsal navicular bone [29]. Magnetic resonance imaging (MRI) delineates the fracture location and status of healing (Fig. 79.2). MRI provides soft tissue definition, which can be helpful in the setting of stress reaction or tendinitis. Although it can confirm the diagnosis in the acute phase, it is generally not indicated initially. MRI findings can help with clinical decision-making about return to activity or play. A retrospective review of military recruits presenting with anterior lower leg pain showed that only 56% had positive findings on MRI testing, implicating tissues other than bone as the pain generator [30]. In a study, 12% of asymptomatic feet in male college basketball players demonstrated bone marrow edema on MRI; the authors noted that this early detection might lead to preventive strategies to avoid injury [31].

MRI grading systems have been developed with short T1 inversion recovery (STIR) sequences. Four grades of abnormality have been described from grade 1 (demonstration of periosteal edema on STIR or T2-weighted images) through grade 4 (visible injury line on T1- or T2-weighted images) [32,33]. Radiographic grading scales of stress injuries to bone can be useful in clinical trials to more specifically delineate response to management. One should consider bone density testing in a female patient with a history of amenorrhea [3].

Differential Diagnosis

- Medial tibial stress syndrome
- Osteoid osteoma
- Compartment syndromes
- Deep venous thrombosis
- Knee disease (e.g., pes anserine bursitis)
- Bone neoplasm
- Osteomyelitis

Treatment

Initial

Pain and edema should be managed initially with PRICE (protection, rest, ice, compression, and elevation). Use of nonsteroidal anti-inflammatory drugs (NSAIDs) is discouraged by several authors because of the negative impact of NSAIDs on tissue healing; in addition, masking of pain can compromise healing by reducing symptomatic feedback [34–37]. Acetaminophen may be helpful in patients who are resting but still have pain. Activities that provoke pain are eliminated. If ambulation is painful, athletes are placed on non-weight-bearing status or full crutch walking to eliminate painful weight bearing [38]. In non-weight-bearing subjects, a trial of walking is performed every 2 days, and once walking is pain free, full ambulation with crutches is begun. Fractures with the propensity to progress to nonunion, such as midshaft tibial stress fractures and tarsal navicular fractures, may require immediate immobilization with a bivalved orthotic boot. Femoral neck fractures on the tension (superior) aspect can become displaced and require strict non-weight-bearing status with axillary crutches initially [39]. Metatarsal stress fractures can be treated with a stiff shoe and a straight cane or a rigid orthosis. Navicular fractures may require immobilization in a short leg cast [34].

In the setting of female athletes with exercise-induced amenorrhea, nutritional counseling and correction of any energy debt must be included in the stress fracture treatment program. If the menstrual cycle does not return with these interventions, there is controversy about the use of an oral contraceptive pill to restore menses. Fewer athletes with fractures were using oral contraceptive pills than were athletes without fractures in one study [40]. In addition, women without stress fractures had a higher intake of calcium than did those with stress fractures. Nine elite runners with stress fractures were compared with matched control subjects without stress fractures, and significant differences in the number of menses per year (less in the fracture group) and the age at onset of menses (delayed in the fracture group) were identified [41].

In the setting of bisphosphonate-related stress fracture in the femoral subtrochanteric or high diaphyseal region, there is still debate as to whether it should be treated nonoperatively or operatively. A study suggested prophylactic fixation because eventually these fractures may become complete and displaced, requiring an eventual fixation [22].

Rehabilitation

Physical therapy modalities such as heat and interferential electrical stimulation are used to increase local blood flow and to promote healing; however, there is a lack of controlled studies to prove their efficacy. Deep soft tissue massage, including transverse friction massage, may be indicated and complement stretching for the muscles that originate along the medial tibia. Ongoing cardiovascular and strengthening activities should continue if they produce no pain; aqua jogging, stationary bicycling, or use of the elliptical machine can be substituted for running. Athletes can return to running once they are pain free with ambulation and cross-training activities; however, training schedules should be modified, and pain should be used as the guide to progression of the program [42]. In the setting of low-risk stress fractures, athletes may continue to participate if activity can be modified to minimize stress at the fracture site [43]. Sports-specific training must be addressed before return to play.

Careful attention to the training surface and equipment is mandatory. In the setting of significant forefoot or rearfoot biomechanical abnormalities, custom foot orthotics may be indicated. Taping may be used temporarily to provide stability of the ankle and foot. Local lower extremity strengthening is progressed from static exercises to concentric to eccentric training on the basis of symptoms. Plyometric (weight-bearing eccentric) training should precede return to play. Shock-absorbing insoles and running on shock-absorbing surfaces are recommended and thought to decrease the ground reaction forces transmitted to the bones of the lower extremity [15,44]. In a prospective study of athletes without control subjects, immobilization with a pneumatic leg brace was used to allow participation in a modified training schedule earlier. The authors concluded that the brace promoted healing and limited the forces across the fracture site [45].

Rock-bottom shoes and steel shanks can be used to prevent and to treat lower extremity stress fractures in susceptible disabled individuals.

Procedures

There is no specific nonsurgical procedure for this injury.

Surgery

Conservative management successfully treats lower extremity stress fractures with a few exceptions. Femoral neck stress fractures on the tensile (superior) aspect may require pinning if they do not heal after a course of non-weight bearing. Midshaft tibial fractures are at risk for nonunion and must be immobilized and observed closely; an open bone grafting procedure may be indicated in the setting of nonunion. Tarsal navicular stress fractures that do

not respond to conservative treatment and demonstrate displacement, comminution, or nonunion may require open reduction with internal fixation [46]. In 26 subjects with 32 fractures treated for 2 years or more, surgical fixation of navicular stress fractures appears to be as effective as conservative management in the longer term [47].

Potential Disease Complications

If biomechanical and training principles are not addressed during treatment, stress fractures can recur. In female athletes with menstrual abnormalities and premature osteoporosis, failure to treat these conditions might also lead to recurrent stress fractures.

Potential Treatment Complications

Immobilization can lead to loss of joint range of motion and reduced muscle strength. Treatment risks with NSAIDs include gastrointestinal, hepatic, and renal side effects; in addition, detrimental effects on bone healing must be considered. A large retrospective study found that use of NSAIDs is associated with a 1.47 relative risk of fractures (nonvertebral) compared with control subjects who did not receive NSAIDs [48]. Treatment of amenorrhea with oral contraceptive pills involves increased risk for blood clots and their sequelae. Treatment of premature osteoporosis with bisphosphonates includes risk for esophageal erosion or ulceration. Complications of surgery include nonunion and other typical infrequent complications (e.g., infection, bleeding). Subjects who underwent surgical treatment for tarsal navicular stress fracture were more likely to continue to be tender over the navicular than were nonoperative subjects [47].

Total Knee Replacement

Thomas E. Groomes, MD

Synonyms

Total knee arthroplasty
Total knee implant
Unicompartmental knee arthroplasty
Revision knee arthroplasty

ICD-9 Codes

715.16 Osteoarthritis, localized, primary, lower leg
715.26 Osteoarthritis, localized, secondary, lower leg

ICD-10 Codes

M17.10 Unilateral primary osteoarthritis, unspecified knee
M17.11 Unilateral primary osteoarthritis, right knee
M17.12 Unilateral primary osteoarthritis, left knee
M17.5 Other unilateral secondary osteoarthritis of knee

Definition

Arthroplasty involves the reconstruction by natural modification or artificial replacement of a diseased, damaged, or ankylosed joint. The knee joint functions as a complex hinge, allowing flexion, extension, rotation, and gliding. The knee joint itself is made up of three compartments, lateral, medial, and patellofemoral. Disease processes that cause damage to the cartilage of any or all of the three compartments may lead to the need for total knee arthroplasty (TKA). Examples of these diseases include osteoarthritis (idiopathic or traumatic), inflammatory arthritis (e.g., rheumatoid, psoriatic), avascular necrosis, tumors, and congenital abnormalities. The principal diagnoses most commonly associated with total knee replacement procedures

are osteoarthritis and allied disorders (90.9%), followed by rheumatoid arthritis and other inflammatory polyarthropathies (3.4%) [1].

TKA is a procedure that is widely performed for advanced arthropathies of the knee; it consistently alleviates pain, improves function, and enhances quality of life [2]. As the elderly population in the United States grows and indications for the procedure broaden, it is projected that an increasing number of patients will undergo TKA. The most common age group for total knee replacements is 65 to 84 years. Women in this age range are more likely to undergo TKA than are their male counterparts.

Approximately 700,000 TKAs are performed annually in the United States. With the aging of the U.S. population, this number is projected to increase to more than 3 million yearly by 2030 [3]. Younger and more active patients are electing to proceed with TKA.

TKA consists of resection of abnormal articular surfaces of the knee with resurfacing predominantly using metal and polyethylene components. The surgical use of a total condylar prosthesis (replaces all three compartments of the knee) dates to the early 1970s. There are three basic types of TKA: totally constrained, semiconstrained, and totally unconstrained. The amount of constraint built into an artificial joint reflects the amount of stability the hardware provides. As such, a totally constrained joint has the femoral portion physically attached to the tibial component and requires no ligamentous or soft tissue support. The semiconstrained TKA has two separate components that glide on each other, but the physical characteristics of the tibial component prevent excessive femoral glide. The totally unconstrained device relies completely on the body's ligaments and soft tissues to maintain the stability of the joint. The semiconstrained and totally unconstrained knee implants are most often used. In general, the totally unconstrained implants afford the most normal range of motion and gait.

In unicompartmental knee arthroplasty, only the joint surfaces on one side of the knee (usually the medial compartment) are replaced. Unicompartmental knee arthroplasty provides better relief than does a tibial osteotomy and greater range of motion than does a TKA as well as improved ambulation velocity. More recently, the concept of minimally invasive TKA has evolved from the procedures and investigations of unicompartmental knee arthroplasty. The distinctive features include decreased skin incision length, inferior and superior patellar capsular releases (necessary to gain exposure of the entire joint and to mobilize

the patella), lack of patellar eversion (reducing risk of permanent dysfunction of the quadriceps muscle), and no tibiofemoral joint dislocation (minimizing capsular damage and postoperative pain).

The need for longer lasting TKAs continues, given the more active and anticipated longer living patient population. Efforts to design a better, longer lasting knee are focusing on alternative bearings and surfaces to reduce osteolysis. Areas being studied include the use of cross-linked ultrahigh-molecular-weight polyethylene inserts, alternative metal and ceramic bearing surfaces, and different mobile bearing designs. The goals of new designs are to minimize wear debris and to decrease risk of loosening and implant failure. The most important determinant of TKA long-lasting success remains a well-balanced, well-aligned, and well-fixed implantation procedure [4].

The increasing use of TKA has raised several public and clinical policy issues, including apparent racial and ethnic disparities in TKA use [5], broadening indications for TKA to include younger and older patients, and evidence that outcomes are better when TKA is performed in higher volume centers [6]. These issues were partially addressed in the Agency for Healthcare Research and Quality report [7]. That report concluded that there is no evidence that age, gender, or obesity is a strong predictor of functional outcomes. Patients with rheumatoid arthritis show more improvement than those with osteoarthritis, but this may be related to their poorer functional scores at the time of treatment and hence the potential for more improvement. The underlying indication, though, is consistent across all these groups, namely, that advanced osteoarthrosis of the knee compromises functional activities as the patient's knee pain becomes recalcitrant and unresponsive to conservative therapeutic interventions. Absolute contraindications to TKA include knee sepsis or other source of ongoing infection, extensor mechanism dysfunction, severe vascular disease, recurvatum deformity due to muscle weakness, and presence of a well-functioning knee arthrodesis. Relative contraindications may include neuropathic joint, morbid obesity, past history of osteomyelitis around the knee, and skin conditions such as psoriasis within the field of surgery [8].

Symptoms

Refractory knee pain is the most common symptom among patients who undergo TKA. Stiffness, deformity, and instability are symptoms also commonly seen in advanced osteoarthrosis or inflammatory polyarthropathy. In the postoperative period, acute surgical pain is most intense during the first 2 weeks. Disruption and inflammation of the periarticular soft tissues are manifested as a soft tissue stiffness pattern that differs in the severity of limitation of range of motion from the preoperative rigid stiffness of advanced arthrosis. Joint proprioception impairment may give rise to a sense of mild knee instability in the postoperative period. Uncommonly, debris may generate a sense of cracking, popping, or locking.

Physical Examination

Physical examination should include palpation of the knee to evaluate for effusion and joint line tenderness, which

may indicate meniscal disease. Gait pattern should be documented with attention to the possible presence of knee thrust (abnormal medial or lateral movement of the knee), which may indicate ligamentous instability. Preoperative knee range of motion should be recorded to assess the extensor mechanism. Because of the importance of preserving the medial and lateral collateral ligaments during a total knee replacement, preoperative assessment of the stability of these ligaments is indicated. The skin over both legs should be assessed for signs of vascular disease or infection. The lower back and hip should be examined to rule out referred pain to the knee [9].

Functional Limitations

Osteoarthritis of the knee can result in pain or stiffness that can affect a person's functional ability to rise from a chair, to walk, or to use stairs. Table 80.1 depicts the required knee range of motion for specific functional mobility tasks. In an otherwise healthy patient population, osteoarthritis may impede participation in recreational or sporting activities, such as golf or tennis. The preoperative profile of a patient at risk for poor postoperative locomotor recovery is a woman with a high body mass index, many comorbidities, high intensity of knee pain, restriction in flexion amplitude, deficits in knee strength, and poor preoperative locomotor ability as measured by the 6-minute gait test. In addition, the preoperative gait power profiles, on the nonsurgical side, are characterized by low concentric push-off work by the plantar flexors and low concentric action of the hip flexors during early swing [10]. Postoperative pain scores and their associated psychological profiles ostensibly affect functional outcomes also [11].

Subsequent studies have further identified factors associated with a suboptimal postoperative functional outcome. Patients who have marked functional limitation, severe pain, low mental health score, and other comorbid conditions before TKA are more likely to have a worse outcome at 1 year and 2 years postoperatively [12]. One consistent finding is that preoperative joint function is a predictor of function at 6 months after TKA. Those patients who had lower preoperative functional status related to knee arthritis functioned at a lower level at 6 months than did patients with a higher preoperative functional status [13]. Studies have focused on quadriceps strength as a significant contributing factor. Functional measures underwent an expected decline early after TKA, but recovery was more rapid than anticipated and long-term outcomes were better than previously reported in

Table 80.1 Required Knee Range of Motion

Activity of Daily Living	Extension-Flexion
Walking in stance phase	15-40 degrees
Walking in swing phase	15-70 degrees
Stair climbing step over step	0-83 degrees
Standing up from a chair	0-93 degrees
Standing up from a toilet	0-105 degrees
Stooping to lift an object	0-117 degrees
Tying a shoelace	0-106 degrees

Modified from Kaplan RJ. Total knee replacement. In Frontera WR, ed. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.

the literature in patients with higher baseline quadriceps strength. The high correlation between quadriceps strength and functional performance suggests that emphasis on postoperative quadriceps strengthening is important to enhance the potential benefits of TKA [14]. However, preoperative quadriceps strength training has not been proved to enhance long-term functional outcome after TKA [15,16].

Diagnostic Studies

Plain radiographs of the knee remain the mainstay of diagnosis and preoperative planning. Three basic views include standing anteroposterior view (assesses medial and lateral joint space narrowing during normal leading of the joint), lateral view (assesses the patellofemoral joint and the position of the patella), and tangential patella or sunrise view (assesses the patellofemoral joint space) [9]. Magnetic resonance imaging is more sensitive than plain radiography in assessing cartilage but still may underestimate the amount of damage. Magnetic resonance imaging may also be used to evaluate meniscal or ligament disease [17].

In addition to the standard preoperative screening for surgical clearance, consideration should be given to radiographic evaluation of the cervical spine in rheumatoid arthritis patients. Rheumatoid arthritis patients are at increased risk for atlantodental instability and therefore may be at increased risk for spinal cord impingement as a result of perioperative manipulations with surgery and general anesthesia [18].

Rheumatoid arthritis patients are thought to be at 2.6-fold greater risk of infections than osteoarthritis patients are. Therefore, rheumatoid arthritis patients should be screened for potential sources of infections, including urinary tract infections, skin infections, and dental infections, before TKA. [19]

Differential Diagnosis of the Symptomatic Total Knee Arthroplasty

- Prosthetic loosening
- Infection
- Periprosthetic fracture
- Component failure

Treatment

Initial

Medical therapeutic interventions address the following.

Prophylaxis for Deep Venous Thrombosis and Pulmonary Embolism

Warfarin, a vitamin K antagonist, can be started preoperatively or postoperatively to prevent deep venous thrombosis (DVT) and pulmonary embolism (PE). The anticoagulant effects of vitamin K antagonists are not achieved until the third or fourth day of treatment. Thus, postoperative initiation of warfarin may not prevent small thrombi from forming. Nevertheless, warfarin does appear to effectively inhibit the extension of small thrombi, thereby preventing clinically significant DVT or PE. Because of its delayed reaction and its similar bleeding rates to low-molecular-weight heparin,

warfarin tends to be the preferred thromboprophylactic medication by United States orthopedic surgeons [20].

New oral antithrombotic agents that inhibit either activated factor X or activated factor XI (thrombin) are now approved for use in the United States. Rivaroxaban inhibits activated factor X. The RECORD3 study demonstrated the superiority of a 10-mg once-daily oral dose of rivaroxaban over 40-mg subcutaneous daily dosing of enoxaparin in reducing the incidence of symptomatic venous thromboembolism (VTE) after total knee replacement [21]. The RECORD4 study compared rivaroxaban 10mg orally daily with enoxaparin 30mg subcutaneously twice daily. No statistically significant difference was shown in the incidence of major or symptomatic VTE [22].

Dabigatran etexilate is a direct thrombin inhibitor. It is active against both free and clot-bound thrombi. The REMOBLIZE trial compared dabigatran with enoxaparin (30mg subcutaneously twice daily). Data for major VTE or death and major bleeding events were comparable [23]. Low-molecular-weight heparins are used in VTE prophylaxis after TKA. They have an advantage in that they can be given subcutaneously once or twice daily with constant dosing without the need for daily laboratory monitoring. They also carry a significantly reduced risk for heparin-induced thrombocytopenia compared with unfractionated heparin.

Intermittent pneumatic compression prevents venous thrombosis by increasing venous blood flow in the deep veins of the legs and by reducing plasminogen activator inhibitor [24]. Intermittent pneumatic compression is contraindicated in patients with evidence of leg ischemia due to peripheral vascular disease. The optimal use of intermittent pneumatic compression, which includes initiation in the operating room or recovery room, is an alternative option for VTE prophylaxis for patients at a high risk for bleeding. Aspirin is thought to be highly effective in reducing major arterial thrombotic events, but the benefit in reducing VTE is less clear. The 2008 American College of Chest Physicians anticoagulation guidelines recommended against use of aspirin alone as prophylaxis for VTE for any medical or surgical patient group [25]. The 2012 American College of Chest Physicians guidelines, however, have included aspirin as a recommended agent for thrombosis prophylaxis in patients undergoing TKA. This recommendation was not unanimously supported by the entire panel [26].

For patients undergoing total knee replacement, UpToDate recommends extending thrombosis prophylaxis beyond 10 days and up to 35 days after surgery [20].

Postoperative Care

During the first 48 to 72 hours, patients often receive controlled analgesia therapy administered through the intravenous or epidural route. Some anesthesiologists use a perioperative femoral nerve block. Subsequently, patients are given oral opioids. Controlled-release and short-acting opioids may be used. Depending on the clinician's and patient's preferences, fixed or rescue dose opioid medications are selected. The opioids can be titrated to achieve balance of analgesia versus emerging side effects [27–30].

Dry, sterile gauze dressings are applied as long as drainage is present. Staples and sutures can safely be removed 10 to 14 days after surgery [31,32]. Knee immobilizers may be used postoperatively to maintain knee extension and to avoid

flexion contracture. Range of motion exercises supervised by a physical therapist should be initiated as soon as possible. Properly fitting, thigh-high elastic compression stockings, a continuous passive motion (CPM) machine, and possibly local cryotherapy are used to manage swelling [33–36].

The overall blood lost after unilateral TKA has been estimated at 2.2 units. Blood loss is greater for uncemented than for cemented prostheses. Patients are often advised before surgery to donate 1 to 3 units of packed red blood cells for autotransfusion, although this practice has recently been questioned [37]. In addition, postoperative blood collection and reinfusion through the surgical drain have been shown to be effective in reducing the need for bank blood and have a low morbidity rate with current techniques. Some patients are advised to commence a course of recombinant erythropoietin in conjunction with iron supplementation before surgery [38]. If the patient is receiving oral anticoagulation therapy, bridging therapy with a low-molecular-weight heparin compound may be considered by the patient's primary care physician or medical consultant [39]. If the perioperative red blood cell count reveals a macrocytic anemia, vitamin B₁₂ and folic acid levels should be obtained. If the anemia is microcytic, serum iron level, total iron-binding capacity, or transferrin concentration should be determined along with a reticulocyte count.

Rehabilitation

Because preoperative function is a strong overall predictor of postoperative function for patients undergoing TKA, researchers are examining the potential role of prehabilitation (presurgical rehabilitation) in improving patient outcomes. Programs may include strength and flexibility training as well as nutritional counseling and education. Outcomes being studied include mobility, pain, self-care function, health-related quality of life, and self-efficacy (defined as the perception of one's ability to perform a task successfully). Although prehabilitation programs can have a positive effect on strength, function, and psychological health before surgery, it remains to be determined whether there is any significant long-term postoperative benefit [16,40].

The focus of postoperative rehabilitation should be joint range of motion, quadriceps strengthening, and training in gait and activities of daily living.

Rehabilitation programs that use clinical pathways enhance the efficiency of postoperative rehabilitation for the patient with TKA. The rehabilitation program can be conceptualized as occurring in stages or phases. The first stage commences in the immediate postoperative period. The final stage concludes when the patient returns to the community and pursues optimal independent functional living. See Table 80.2 for an example of a clinical pathway that addresses the schedule of progression during the first phase.

CPM devices may be used, but there is uncertainty whether the cost and inconvenience justify any significant clinical benefits. A 2010 meta-analysis review of 20 random trials comparing routine postoperative physical therapy and care with CPM to routine postoperative physical therapy and care without CPM showed only a small increase in range of motion (2–3 degrees) in the CPM group [41]. There is no evidence that short-term CPM application versus long-term CPM application influences outcome. There is no substantial

evidence that CPM influences the degree of swelling, risk of VTE, or incidence of wound infection or incision site complications [42]. In the immediate postoperative period, the inhibited quadriceps and hamstrings may not adequately stabilize the knee. The patient may require a knee immobilizer for transfers and walking. The patient will often require a two-handed assistive device (e.g., walker or axillary crutches) for gait training initially. Adaptive equipment for bathing and dressing (e.g., tub or shower seat, grab bars, dressing sticks, sock aid) is generally necessary. Some patients may not have sufficient range of motion during the first week postoperatively to negotiate stairs. The motor reactions normalize by the third week; therefore, patients may return to driving activities if they can perform car transfers independently and can tolerate sitting for prolonged periods [43].

During the second stage of TKA rehabilitation (weeks 1 to 4), the patient progresses to low-resistance dynamic exercise for the involved lower extremity. This can be carried out with a stationary bicycle. Some patients may prefer aquatic-based exercise regimens during this period. Patients should be independent in ambulating with a two-handed or single-handed device if they are fully weight bearing on level surfaces up to 500 feet. They should be supervised in negotiating stairs. Electrical stimulation of the quadriceps can be considered for patients who have inhibited recruitment [44]. Soft tissue mobilization can be introduced to facilitate patellar glide. During this period, the patient should be independent in all basic activities of daily living. During the last 10 years, there has been a significant temporal shift in expediting home and outpatient (clinic) TKA rehabilitation. In this regard, there are no reproducible and enforceable guidelines that may be uniformly applied [45–47].

During the third stage of TKA rehabilitation (weeks 4 to 8), the available range of motion should reach 0 to 115 degrees. Patients are able to advance their dynamic resistance exercise regimens and more freely pursue both open and closed kinetic chain and dynamic balance exercises. Patients advance to a single-handed device or no device for ambulation and at different speeds and on different terrain. They should be independent in negotiating stairs. Patients advance to independence in instrumental activities of daily living.

In the final stage (weeks 8 to 12), patients may return to their preoperative exercise regimens and recreation activities and kneeling. Most patients who participated in sports before surgery are able to return to low-impact sport activities and exercise regimens. Patients are able to return to sedentary, light, and medium work categories. Patients who are on sick leave for more than 6 months preoperatively are less likely to return to work. There is published evidence that the degree of physical activity does not contribute to premature revision TKA [48]. However, younger patients may be at risk for earlier revision TKA, depending on their degree of physical activity [49]. Contact sports are advised against, and caution should be exercised with high-impact aerobic activities [50–54].

Procedures

Manipulation

Some patients with unsatisfactory gains in knee range of motion may be candidates for manipulation. The role of manipulation for the patient with a TKA contracture remains

Table 80.2 Clinical Pathway for First-Phase Rehabilitation

Postoperative Day	Exercise	Mobility	Ambulation	Activities of Daily Living
0	Deep breathing Incentive spirometer Quadriceps and gluteal sets	Sits to chair transfer Education on continuous passive motion machine		
1	Straight-leg raise Hip abduction Ankle pumps Deep breathing	Bed mobility		Assess adaptive equipment: reachers, long-handled sponges, and shoehorns
	Lower extremity static resistance exercises Ankle pumps and circles Continuous passive motion	Bed to chair transfers with knee immobilizer		
2	Continue previously described exercises	Continue bed mobility and transfers	Assisted ambulation in room, partial weight bearing or weight bearing as tolerated with knee immobilizer	Raised toilet seat
	Short arc quads			Grooming and dressing well while seated
	Straight-leg raise with knee immobilizer Upper extremity strengthening	Begin toilet transfers		
3	Continue previously described exercises	Decreased assistance in basic transfers	Independent ambulation with walker or crutches in room, partial weight bearing or weight bearing as tolerated with knee immobilizer	Independent toileting and grooming
	Sitting full arc motion flexion and extension in conjunction with supine passive flexion and extension		Trial of ambulation in corridor, possibly practice negotiating 2-4 stairs	Education on joint protection and energy conservation techniques
Depending on community resources and home safety and support availability, the patient may be ready for hospital discharge and post-acute care rehabilitation at this time.				
4	Continue previously described exercises with increased intensity	Independent in basic transfers	Gait training to improve pattern and endurance Discontinue knee immobilizer (if quadriceps strength is greater than 3/5)	Continue previously described activities of daily living
	Initiate active assistive range of motion exercises and quadriceps and hamstrings self-stretch			
5-6	Continue previously described exercises		Independent ambulation with assistive device	Independent dressing with tapered use of adaptive equipment
	Transition from passive to active assistive range of motion exercises		Begin stairs with railing, cane as needed	

From Kaplan RJ. Total knee replacement. In Frontera WR, ed. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.

controversial. Outcome studies are divided as to whether functional outcomes and quality of life are enhanced as a result of manipulation. When an orthopedic surgeon performs the procedure, it is carried out in an operating room with the use of general or epidural anesthesia. The goal is to

overcome articular lesions with minimal force after quadriceps resistance is eliminated. Manipulation is most commonly performed during the second or third postoperative week if the range of motion of the involved knee is less than 75 degrees [55,56].

Arthrocentesis

Aspiration of the knee for aerobic and anaerobic cultures and sensitivities is the most reliable method for diagnosis of infection. Strict sterile technique must be used throughout the aspiration procedure [57].

Surgery

The most common materials presently used in replacement joints are cobalt-chromium and titanium on ultrahigh-molecular-weight polyethylene. In total knee arthroplasties, cobalt-chromium is commonly used on femoral weight-bearing surfaces because of its superior strength. Total knee arthroplasties can be stabilized with or without cement. In some cases, hybrid total knee arthroplasties are used.

There are three major surgical approaches for the standard TKA: the medial parapatellar retinacular approach, the midvastus approach, and the subvastus approach [58]. The medial parapatellar retinacular approach compromises the quadriceps tendon in its medial third, and this gives rise to more postoperative patellofemoral complications. The midvastus approach does not compromise the extensor mechanism of the knee joint. The subvastus approach also preserves the integrity of the extensor mechanism but does not expose the knee as well as the other two approaches do. The type of arthrotomy used will influence postoperative management. After a standard anteromedial arthrotomy between the vastus medialis and rectus tendons with eversion of the patella, active and passive range of motion may begin immediately. Protected ambulation with crutches or a walker is recommended for 4 to 6 weeks to allow healing of the arthrotomy repair and recovery of quadriceps strength. Although recovery after the subvastus approach may be more rapid than after the standard anteromedial approach, protected weight bearing with ambulatory aids for 3 to 6 weeks is still recommended to allow soft tissue healing. In the patient with limited preoperative range of motion, either tibial tubercle osteotomy or a V-Y quadricepsplasty needs to be performed. After tibial tubercle osteotomy, early range of motion and full weight bearing within 1 week of surgery is recommended. Variations of the conventional surgical exposures are also used in the minimally invasive TKA operative approaches [59].

Weight-bearing status depends on the details of the surgical reconstruction and whether the components were inserted with or without cement. For the otherwise uncomplicated primary cemented TKA, the patient can tolerate weight bearing within the confines of safety. Protected weight bearing can be performed only after the patient demonstrates adequate control of the limb to prevent falling. The time to weight bearing after total arthroplasty depends on the use of cement or cementless fixation and whether large structural bone grafting was required. In cemented total knees, no differences in the incidence of radiolucent lines have been observed between immediate weight bearing and protected weight bearing for 12 weeks. Although weight bearing after cementless fixation might increase micromotion, many surgeons allow early weight bearing [60].

The tibial and femoral components presently in use have a life expectancy of 10 to 20 years. This life span depends on the surgical technique, the components used, the bone stock, and the level of physical activity after TKA. Revision

TKA is a surgical procedure that the patient with TKA may encounter several years after the original surgery [61].

Potential Disease Complications

Potential disease complications of conditions involving the knee, such as osteoarthritis, rheumatoid arthritis, and osteonecrosis of the femoral epicondyle or tibial condyle, include intractable pain, swelling, stiffness, contracture, and valgus or varus deformity. It is recommended that TKA not be significantly delayed once it is clinically indicated. Otherwise, the delay may allow the development of soft tissue contractures and excessive muscle atrophy, which could reduce the chances of a good postoperative recovery [62].

Potential Treatment Complications

The development of DVT with the subsequent risk for fatal PE is understandably the most feared complication of TKA. Without prophylaxis, the incidence of DVT after TKA ranges from 40% to 88%, the incidence of asymptomatic PE ranges from 10% to 20%, and the incidence of symptomatic PE ranges from 0.5% to 3%, with mortality up to 2%. With prophylaxis, the incidence of symptomatic DVT and PE drops to less than 1% and 0.3%, respectively [63].

Patellofemoral complications are thought to be the most common reason for reoperation after TKA. Examples include patella instability, patella component loosening or failure, patella fracture, patella clunk syndrome, and rupture of the extensor mechanism. Patella clunk syndrome results from formation of fibrous tissue on the quadriceps tendon. The patient feels a clunk as the knee is actively extended from 60 to 30 degrees. This syndrome was more commonly seen with earlier designs of posterior cruciate substitution prostheses. With changes in component design, the incidence of patella clunk has decreased [64].

The most common neurologic complication is peroneal nerve palsy. Clinical presentation includes paresthesias and ankle dorsiflexion weakness. Incidence is less than 1%. Recovery is variable, with one study reporting up to 50% full recovery [8]. Arterial vascular injuries, the majority of which are thrombosis, are exceedingly rare.

Periprosthetic fractures may occur in the patella, around the femoral component and the tibial component. Osteoporosis and rheumatoid arthritis increase the risk for periprosthetic fractures. Femoral fractures are associated with notching of the anterior femur at time of surgery. Tibial fractures remain rare [64].

Arthrofibrosis (stiffness) is a postoperative limited range of motion that may result in decreased function. In general, 67 degrees of knee flexion is needed during the swing phase of gait, 83 degrees to ascend stairs, 100 degrees to descend stairs, 93 degrees to rise from a standard chair, and 105 degrees to rise from a low chair [65]. It remains unclear whether the use of continuous passive motion reduces the risk of arthrofibrosis.

Although infection is a serious complication, the overall infection rate for initial TKA is low at around 1% [66]. This is higher in patients with diabetes mellitus, advanced rheumatoid arthritis, revision TKA, or constrained prostheses. Deep infection can occur any time from days to months after surgery. Musculoskeletal infection usually is manifested

as increase in pain with or without weight bearing, increase in swelling, and fever. Diagnosis is confirmed by joint fluid analysis, as described earlier. The patient typically requires at least a 6-week course of antibiotic treatment between the period of component removal and reimplantation. The most successful technique for treatment of the infected total knee replacement is a two-stage reimplantation of the TKA components. Infection must never be overlooked as a cause of implant loosening. Infection can occur early or late and can be manifested with or without signs of systemic toxicity. The symptoms are commonly the same as those seen with aseptic loosening. A progressive radiolucency between the prosthesis and its adjacent bone almost always is considered an infection until proved otherwise. Negative aspirate from the knee, normal sedimentation rate and C-reactive protein level, and normal gallium or indium scans cannot rule out infection of the prosthetic device. The patient should be advised that even in the presence of normal test results, infection of the prosthetic device may be discovered intraoperatively and necessitate the removal of the prosthetic device.

Metallosis is a rare but severe complication of knee replacement surgery. Metallic debris may be deposited in the periprosthetic soft tissues from abrasion of the metallic components. This metallic debris may induce a massive release of cytokines from inflammatory cells. This release may accelerate osteolysis and loosening of the prosthesis [67]. The inflammatory cells may also infiltrate the synovium, resulting in synovitis, which may be manifested as an acutely painful effusion [68]. In addition, the metallic debris may have a direct toxic effect on human marrow stroma-derived mesenchymal stem cells; it is hypothesized that decreased viability of these mesenchymal stem cells may reduce the amount of viable osteoprogenitor cells, which would be a factor in the development of poor periprosthetic bone quality. The reduction in bone quality increases the risk of implant stability, which eventually requires revision surgery [69]. Titanium components appear to have an increased association with metallosis in comparison to chromium-cobalt components [68].

The most common reason for total arthroplasty failure has been loosening of the implant. Factors associated with loosening include infection, implant constraint, failure to achieve neutral mechanical alignment, instability, and cement technique. The prodromal features of impending loosening and failure of the components are an increase in pain and swelling with or without angular deformity of the knee [70]. The radiographic features include a widening radiolucent zone between the implant and the adjacent bone and subsidence of the implant. Loosening may occur at the component-cement interface or bone-cement interface. Implant loosening can be attributed to mechanical and biologic factors. The mechanical factors include limb alignment, ligamentous balance, and preservation of a contracted posterior cruciate ligament. Implant loosening can occur early or late. Early implant loosening usually occurs within the first 2 years and represents a mechanical failure of the interlock of the implant and host to bone. This early implant loosening is more appropriately called fixation failure and is often secondary to errors in judgment at the time of surgery or to problems with the technical aspects of the surgical procedure. Extremity malalignment, soft tissue imbalance,

and poor cement technique individually or in combination contribute to loosening. Biologic factors are largely responsible for the phenomenon of late loosening. Late loosening of total knee implants is often secondary to the host biologic response to the implant's debris that weakens the mechanical bond of implant to bone established during surgery. Mechanical factors may contribute to late loosening, but they do not alone explain the loss of a fixation device that has been stable for many years. The volume of particles generated from the articulation is influenced by the patient's weight and activity level, duration of implantation, polyethylene thickness, and contact stresses. Wear may be accelerated by malalignment, instability, and ligament imbalance, resulting in increased volume of particulate released into the joint [71]. Aseptic loosening that will lead to failure of the prosthesis occurs in 5% to 10% of patients at around 10 to 15 years after surgery. Once a component becomes loose, it becomes mechanically unstable. This can lead to increased osteolyses. If the osteolyses becomes severe, revision surgery will be difficult [8]. Thirty-day mortality for TKA is around 0.6%, with no significant differences based on race or ethnicity [9].

SECTION IX

Foot and Ankle

CHAPTER 81

Achilles Tendinopathy

Michael F. Stretanski, DO

Synonyms

Achilles tendinosis
Peritendinosis
Heel cord tendinitis

ICD-9 Codes

726.71 Achilles bursitis or tendinitis
845.09 Sprains and strains of ankle and foot,
Achilles tendon

ICD-10 Codes

M76.60 Achilles tendinitis, unspecified leg
M76.61 Achilles tendinitis, right leg
M76.62 Achilles tendinitis, left leg
S96.811 Sprain of other specified muscles and
tendons at ankle and foot level,
right foot
S96.812 Sprain of other specified muscles and
tendons at ankle and foot level,
left foot
S96.819 Sprain of other specified muscles and
tendons at ankle and foot level,
unspecified foot
Add the appropriate seventh character for
episode of care to S96

Definition

Achilles tendinopathy exists along a spectrum of peritendinitis to tendinosis or tendinopathy. The pathologic process involves a painful, swollen, and tender area of the Achilles

tendon and peritenon. Athletes with particularly tight heel cords are predisposed to this injury. This condition commonly affects middle-aged men who play tennis, basketball, or other quick start-and-stop sports. Achilles tendon rupture carries a 200-fold risk of sustaining a contralateral rupture of the Achilles tendon [1], but atraumatic disease associations, such as periarticular manifestation of poststreptococcal reactive arthritis [2], should remain in the atraumatic differential. Collagen vascular disease, inflammatory disease, and diabetes may also be risk factors. The relative avascularity of the region 5 to 7 cm proximal to the calcaneus insertion has long been considered a pathoanatomic structural risk factor, as is the thinning and twisting of the tendon at this midsection [3]. However, morphologic and biochemical differences present within the tendon during Achilles tendinopathy provide a modern addendum to this dogma. Upregulation of collagen 1 and collagen 3 together with mRNA of fibronectin, tenascin C, and fibromodulin as well as degradation factors matrix metalloproteinases 2 and 9 and tissue inhibitor of matrix metalloproteinase 2 in Achilles tendinopathy [4] seem to add to the growing understanding of the cellular and molecular basis of the clinical presentation. The histopathologic feature is angiofibroblastic hyperplasia (tendinosis) of the body of the tendon (a degenerative process) with a concomitant and potentially secondary inflammatory response in the peritenon [5,6]. The maladies often occur simultaneously but may occur individually. An association with chronic quinolone exposure is well documented [7–9] and is worse in patients concomitantly taking prednisone long term.

Symptoms

Pain and tenderness in the Achilles tendon are predominant symptoms, usually in association with running, sports with quick “cutting,” and other fitness activities [10]. Activities with rapid starting and stopping or rapid eccentric contraction, such as classical ballet [11], increase the symptoms and risk of complete tear. In some patients, the pain actually improves with lower extremity exercise. Typically, the

pain occurs with a change in activity or training schedule. The most common location for tendinosis symptoms is at the apex of the Achilles tendon curvature. Different activities can lead to pathologic change in other regions of the tendon, namely, at the calcaneal insertion with or without a Haglund deformity or at the myotendinous junction. A history of an acute traumatic event in which the patient reports a “pop” should suggest an Achilles tendon tear, although a similar pop can occur with tear or rupture of the plantaris, peroneus, or posterior tibial tendon. History of quinolone exposure, diabetes, collagen vascular disease, anabolic steroid use, or smoking should be noted.

Physical Examination

The essential element in the physical examination is localization of swelling and tenderness in the critical zone of the Achilles tendon at the apex of the Achilles curve approximately 2 ½ inches proximal to the os calcis insertion. Exquisite tenderness to palpation is a classic examination finding. The degree of ankle plantar force generated has been shown to have a strong negative relationship with pain, and a standardized strength testing system has been suggested and shown to be reliable on a small sample of patients [12]. Palpable heat is usually not evident unless peritendinitis is a major component. The Achilles tendon is usually tight, with ankle dorsiflexion rarely extending beyond 90 degrees. Associated findings may include abnormal foot posture (pes planus or cavus), tight hamstrings, and muscle weakness of the entire hip and leg. Heels may not move into a normal varus position in standing on toes. Neurologic evaluation findings, including strength, sensation, and deep tendon reflexes, are normal.

The examination should also include observation for a palpable defect and the Thompson test (squeezing the calf, which should result in plantar flexion in an attached tendon) to rule out rupture of the Achilles tendon (Fig. 81.1).

Functional Limitations

Impact weight-bearing activities, such as jogging and running, are usually limited. Dance or cutting “moves” typical of field sports are virtually impossible. Nonimpact fitness activities, such as cycling and using an elliptical trainer, may also result in symptoms. Patients may complain of pain with daily ambulatory activities, such as walking at work or climbing stairs. Whereas individual differences exist, early recovery of plantar flexion may be seen with little functional change, usually because of flexor hallucis longus compensation [13].

Diagnostic Studies

Unless a special form of calcified Achilles tendinosis occurs at the os calcis insertion, regular radiographs are usually normal. Diagnostic ultrasonography or magnetic resonance imaging is capable of defining the extent of both tendinosis and peritendinitis, but serial magnetic resonance examinations, especially postoperatively, are not indicated and do not correlate with functional outcome [14]. Partial rupture is a diagnostic dilemma for diagnostic ultrasonography [15], and if it is suspected, magnetic resonance imaging should still be considered the standard of care. Magnetic resonance imaging is also more useful in documenting a complete tear’s distance and location as well as the existence of partial tear that may appear

FIGURE 81.1 The Thompson test is a reliable clinical test to identify a complete tear in the Achilles tendon. When the Achilles tendon is torn, a positive test result is elicited by squeezing the calf and seeing no plantar flexion of the foot. The test result is negative when the calf is squeezed and plantar flexion occurs in the foot.

normal or questionable on diagnostic ultrasound examination. Electrodiagnostic studies, especially needle electromyography and H reflexes (the electrodiagnostic equivalent of an Achilles muscle stretch reflex), may help in defining S1 radicular features, but a normal electrodiagnostic study does not rule out sensory irritative radiculitis. These studies are generally recommended only to help define the prognosis or in patients who are unresponsive to rehabilitation and for whom surgery or other diagnoses are being considered. A slowly evolving role of positron emission tomography may exist [16], and blood work germane to systemic disease, sedimentation rate, antinuclear antibody, rheumatoid factor, and antistreptolysin antibody titer [2] may be appropriate.

Differential Diagnosis

- Haglund deformity
- Retrocalcaneal bursitis
- Adventitial bursitis
- Achilles tendon rupture
- Tibial stress fracture
- Medial gastrocnemius tear
- S1 (L5) radiculopathy

Treatment

Initial

The initial treatment goal is to decrease pain and to reduce inflammation when it is present. Therefore rest from aggravating

activities is critical. Icing (20 minutes, two or three times daily) and nonsteroidal anti-inflammatory drugs or analgesics can be used for pain and inflammation. A wide range of treatments from repetitive low-energy shock wave treatment [17], sclerosing agents [18], and topical nitroglycerin [19] to low-level laser therapy have been attempted with varying degrees of mixed results in small studies.

Counterforce bracing is often helpful, or a simple heel lift ($\frac{1}{8}$ to $\frac{1}{2}$ inch) can decrease stress on the tendon. Warm-up before any weight-bearing activity and cooling with ice afterward are recommended. Good functional results can usually be achieved in about 75% of cases at 3 months with nonoperative treatment in compliant patients with a tendon separation distance of 10 mm or less apparent on diagnostic ultrasonography [20].

Rehabilitation

The rehabilitative process focuses on biologic improvement of the damaged tendon and peritenon and restoration of function, rather than the comfort efforts of the initial treatment phase. Rehabilitation is best initiated in a structured physical therapy program followed by home therapeutic exercise. Non-weight-bearing status and axillary crutches may have a role in the acute phase of treatment, with return to weight bearing as tolerated. A short leg cast or splint in 10 to 15 degrees of plantar flexion may also have a short-term role in acute phase treatment. Passive modalities including therapeutic ultrasound, iontophoresis, and phonophoresis often enhance compliance and enable the rehabilitation program. Electrical stimulation should be considered contraindicated in the face of the overuse etiology and counterphysiologic motor unit recruitment of muscle fibers.

Therapeutic exercise needs to be directed toward the complete kinetic chain because strength, endurance, and flexibility deficits are common, and most lower extremity sports activities occur as patterned motor engrams. Strength, proprioceptive, and endurance testing usually aids in uncovering relative weaknesses and monitoring the rehabilitation progress. Controlled eccentric exercise may be of benefit throughout the strength-building phase of rehabilitation and avoid additional tendon separation.

Control of abusive force loads can be accomplished by counterforce bracing of the Achilles tendon or orthotics to minimize abnormal foot posture. Gradual, controlled return to running may be initiated through running in water programs. As with any lower extremity injury, general fitness may be maintained by use of upper body land programs such as arm ergometry, resistance training, and water programs dedicated to the entire body. Return to sport or running is transitional, including plyometric and eccentric exercises. Full return generally requires normal strength, endurance, and flexibility. Repeated injury is not uncommon. Return to normal activity, generally in 6 to 12 weeks, depends on level of participation (professional athlete versus weekend warrior), severity of the injury, and general medical condition.

Procedures

Exogenous glucocorticoid injection is contraindicated as cellular death and tendon weakness with potential progression to tendon rupture are significant concerns. Although there may be a developing role for hyaluronate G-F 20 [21], this

has been studied, to date, only in corticosteroid-induced Achilles tendinopathy in an animal model. Likewise, pulsed ultrasound [22], indium-gallium-aluminum-phosphide diode laser irradiation [23], and substance P injection [24] in an animal tenotomy model have all shown potential results, and hyperbaric oxygen [25] may have a slightly more promising role.

Surgery

Rehabilitation failure may invite surgical intervention with a goal of problem resolution versus acceptance of the malady and alteration of activity level. Optimal surgical management strategy is controversial, but the relative avascularity of the region makes wound healing complications and deep infection ever-present threats. The concepts of surgery include removal of symptomatic peritendinitis tissue and resection of the abnormal tendinosis tissue in the body of the Achilles tendon with subsequent repair of the remaining adjacent normal tendon. This is usually accomplished with standard sutures or wires; however, fibrin sealant has been used [26], and at least on the surface, this may seem a more biologic approach. Surgical options consist of open, mini-open, or percutaneous repair. Surgery outcomes are better if all pathologic tissue is removed, reanastomosis is performed, and appropriate postoperative rehabilitation is implemented. The postoperative goals of neovascularization, reduction of atrophy, fibroblastic infiltration, and collagen production and the restoration of strength, endurance, and flexibility are best served by early mobilization [27].

In cases of suspected tendon rupture, a surgical consultation is warranted for consideration of other tendon ruptures. Endoscopic techniques have evolved alongside open and mini-open [28] approaches but with comparable re-rupture rates. The percutaneous repair seems to be a better option for elite athletes with a greater likelihood of return to sport activities [29], but it has an increased complication rate. There are differences of opinion as to whether the percutaneous technique should be performed at all in lieu of a limited open technique [30].

Potential Disease Complications

Chronic symptoms can result in weakening and subsequent complete rupture of the Achilles tendon. Chronic intractable pain with other kinetic chain imbalances and secondary gait abnormality may develop. Significant alterations in gait can cause secondary knee, hip, forefoot, or low back pain. Consideration of undiagnosed systemic diseases that carry their own comorbidities should be entertained.

Potential Treatment Complications

Side effects of nonsteroidal anti-inflammatory drugs include gastric, renal, and hepatic complications. Bracing for prolonged periods may lead to pressure sores, disuse weakness, atrophy, poorly coordinated motor control when return to activity is attempted, and potential peroneal neuropathy. Sural nerve injury can occur with open or percutaneous repair [31]. Overly aggressive physical therapy or electrical stimulation of the gastrocnemius-soleus complex may cause

increased pain and inflammation that can ultimately lead to tendon weakness and potential rupture. Surgical complications of bleeding, infection, and tibial, peroneal, or sural nerve injury are well known. Repeated tear may occur.

Ankle Arthritis

David Wexler, MD, FRCS (Tr & Orth)

Dawn M. Grosser, MD

Todd A. Kile, MD

Synonym

Degenerative joint disease of the ankle

ICD-9 Codes

715.17 Osteoarthritis, localized, primary, ankle and foot

715.27 Osteoarthritis, localized, secondary, ankle and foot

716.17 Traumatic arthropathy, ankle and foot

ICD-10 Codes

M19.071 Primary osteoarthritis, right ankle and foot

M19.072 Primary osteoarthritis, left ankle and foot

M19.079 Primary osteoarthritis, unspecified ankle and foot

M19.271 Secondary osteoarthritis, right ankle and foot

M19.272 Secondary osteoarthritis, left ankle and foot

M19.279 Secondary osteoarthritis, unspecified ankle and foot

M12.571 Traumatic arthropathy, right ankle and foot

M12.572 Traumatic arthropathy, left ankle and foot

M12.579 Traumatic arthropathy, unspecified ankle and foot

Definition

Ankle arthritis is degeneration of the cartilage within the tibiotalar joint that can result from a wide range of causes, most commonly post-traumatic degenerative joint

disease. An acute injury or trauma sustained a number of years before presentation or less severe, repetitive, minor injuries sustained during a longer period can lead to a slow but progressive destruction of the articular cartilage, resulting in degenerative joint disease [1]. Other common types are primary osteoarthritis, inflammatory arthritis (including rheumatoid, psoriatic, and gouty), and septic arthritis. Osteoarthritis is usually less inflammatory than rheumatoid arthritis but can also involve many joints simultaneously.

Symptoms

As with arthritis of any joint, the presenting symptoms are pain (which may be variable at different times of the day and exacerbated by activity), swelling, stiffness, and progressive deformity [1]. The ankle may be stiff on initial weight bearing; this improves after walking a while but then worsens with too much ambulatory activity. The pain is often relieved with rest. Pieces of the cartilage can break off, forming a loose body, and the joint can “lock” or “catch,” sticking in one position and causing acute, excruciating pain until the loose body moves from between the two irregular joint surfaces. Another symptom is that of “giving way” or instability of the joint, which may be a result of surrounding muscle weakness or ligamentous laxity. With progression of the arthritis, night pain can become a major complaint.

Physical Examination

Swelling, pain, and possibly increased temperature on palpation may be present. The pain is usually maximal along the anterior talocrural joint line and typically chronic and progressive. If the patient's other ankle is normal, it is important to compare the two. Deformity and reduced range of motion in plantar flexion and dorsiflexion (normal: up to 20 degrees of dorsiflexion and 45 degrees of plantar flexion) may be seen. The patient may exhibit an antalgic gait or a limp. Acute arthritis is manifested very differently. Onset is rapid with associated warmth, erythema, swelling, and severe pain with passive range of motion and may be accompanied by constitutional symptoms such as fever and rigors.

It is appropriate to examine the other joints in the lower limb, particularly the knee. The findings on neurovascular

examination are typically normal. Decreased sensation in the lower limb raises the possibility of a Charcot joint causing a destructive arthropathy (see Chapter 128).

Functional Limitations

Pain with walking distances and difficulty in negotiating stairs or inclines are particular functional disabilities. Even prolonged standing can become intolerable with advanced joint deterioration. Night pain can lead to disturbance of sleep. Patients will typically adjust their activities or eliminate many of them, particularly exercising, because of pain.

Diagnostic Studies

Plain anteroposterior and lateral standing radiographs provide sufficient information in the later stages of the disease (Figs. 82.1 and 82.2). Magnetic resonance imaging may show damage to articular cartilage and a joint effusion earlier in the course of the disease. In assessment of the radiographs, attention should also be paid to the other joints in the hindfoot because these will affect management options. Generalized bone density and alignment should also be noted.

In some cases, patients present with varying degrees of degeneration of other, adjacent joints, such as the subtalar joint or the knee. By performing differential blocks (i.e., isolated ankle block or subtalar block) with local anesthetic under radiographic control, the clinician may determine which of these joints are symptomatic. A bone scan might be of assistance. In acute presentations, complete blood cell count with a white blood cell count differential, serum urate concentration, and possible joint needle aspiration can help clarify the diagnosis.

FIGURE 82.1 Lateral standing radiograph of the ankle in a patient with rheumatoid arthritis. This demonstrates loss of joint space and bone destruction of the ankle joint.

FIGURE 82.2 Anteroposterior standing radiograph of bilateral ankles in a patient with rheumatoid arthritis. This demonstrates the degenerative, destroyed joint on the left and one method of fusion with an intramedullary nail on the right.

Differential Diagnosis

- Edema (e.g., edema secondary to congestive cardiac failure)
- Subtalar joint degenerative disease
- Posterior tibial tenosynovitis
- Osteochondral defect
- Fracture
- Osteonecrosis

Treatment

Initial

Initial treatment focuses on pain relief and minimizing inflammation. Nonsteroidal anti-inflammatory drugs or simple analgesics are used to alleviate the pain. Prefabricated orthoses ranging from flexible neoprene braces and lace-up or wraparound ankle supports to more rigid braces or walking boots can be prescribed to enhance stability and to reduce movement in the ankle joint, thus reducing pain levels.

Rehabilitation

A custom-molded rigid ankle-foot orthosis fabricated by a skilled orthotist along with a rocker-bottom modification to the shoe (which can be accomplished by most cobblers) can provide dramatic pain relief for most patients with ankle arthritis. A physical therapist can instruct a patient in the proper technique for use of a walking stick or cane in the opposite hand. This is a simple but effective aid in reducing the forces across the ankle joint when the patient is ambulatory.

Mobilization, stretching techniques, and range of movement exercises may help alleviate pain and stiffness. Non-weight-bearing exercises are important, and if it is accessible, hydrotherapy has been shown to be an extremely useful and

productive adjunct. Distraction and gliding mobilization techniques improve range of movement. Strengthening of surrounding muscle groups and proprioceptive rehabilitation will enhance stability.

Procedures

Other than the blocks that are performed to determine the location of the pathologic changes in confusing cases, injections are not typically done for ankle arthritis. Corticosteroid injection is generally of only limited duration, and steroids are chondrotoxic (cause cartilage damage). However, they can provide excellent temporary pain relief in patients with joints at end-stage disease. Viscosupplementation injections (as used in the management of knee arthritis) are still experimental and not recommended at this time.

Surgery

Surgery is indicated in patients who fail to respond to non-operative management and especially in those with unremitting pain. In the earlier stages of arthritis, an arthroscopic washout and cartilage débridement of the ankle joint may provide significant improvement in pain levels.

As the disease progresses, more extensive surgery is required. Many different variations and techniques of fusion have been described, ranging from minimally invasive arthroscopic arthrodesis to open fusion with hardware [1–6]. Distraction arthroplasty (application of an external fixator for a period of time) has shown some promising results. Total ankle joint replacement (arthroplasty) has been an alternative to ankle fusion since the 1970s in certain select populations of patients. It has undergone a series of alterations because the earlier generation models were prone to failure and unpredictable results [7]. In recent times, there have been significant advances in and ongoing research comparing efficacy of arthrodesis and total joint arthroplasty [8,9]. Selection of patients is of paramount importance; those with high expectations and demands (hiking, tennis, running) may be better served with a more predictable, stable fusion than with a replacement that has a high likelihood of failure and need of revision.

Potential Disease Complications

Progressive immobility, permanent loss of motion of the ankle joint, bone collapse leading to leg length discrepancy, and chronic intractable pain can result from ankle arthritis.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Arthroscopy can be complicated by nerve damage or, rarely, septic arthritis. On occasion, with arthrodesis, fusion can fail to occur [10]. An alteration in gait is common [11]. Arthroplasty complications include infection, thromboembolism, bone collapse, and implant migration.

CHAPTER 83

Ankle Sprain

Brian J. Krabak, MD, MBA, FACS

Synonym

Inversion sprain

ICD-9 Code

845.00 Sprains and strains of the ankle and foot

ICD-10 Codes

S93.401 Sprain of unspecified ligament of right ankle

S93.402 Sprain of unspecified ligament of left ankle

S93.409 Sprain of unspecified ligament of unspecified ankle

S93.601 Unspecified sprain of right foot

S93.602 Unspecified sprain of left foot

S93.609 Unspecified sprain of unspecified foot

Definition

Ankle sprain involves stretching or tearing of the ligaments of the ankle. Ankle injuries are a common cause of morbidity in the general and athletic population, with an estimated 25,000 ankle sprains requiring medical care in the United States per day [1]. Overall, ankle sprains are slightly more likely to occur in males (50.3%) than in females (49.7%) and nine times more likely to occur in younger than in older individuals [2]. In the high-school athlete, there are an average of 5.23 ankle injuries per 10,000 athlete-exposures, most often due to traumatic ligament injuries involving boys' basketball, girls' basketball, and boys' football [3]. In the collegiate athlete, ankle sprains represent 15% of all athletic injuries and account for almost 25% of injuries of men's and women's collegiate basketball and women's volleyball athletes [4,5].

Eighty-five percent of all ankle sprains occur on the lateral aspect of the ankle, involving the anterior talofibular ligament and calcaneofibular ligament (Fig. 83.1) [6]. Another 5% to 10% are syndesmotomic injuries or high ankle

sprains, which involve a partial tear of the distal anterior tibiofibular ligament. Identification of syndesmotomic sprains is important; they may have a prolonged recovery compared with milder lateral ankle sprains and are more likely to require surgery. Only 5% of all ankle sprains involve the medial aspect of the ankle as the strong medial deltoid ligament is resistant to tearing. Most ankle sprains will recover during several weeks to months, depending on the grade of injury. It is estimated that 20% to 40% of ankle sprains result in chronic sequelae [7]. An ankle sprain that does not heal may be caused by injuries to other structures and will necessitate further investigation for other causes.

The exact structure torn will depend on the mechanism of injury. The most common mechanism of injury involves foot supination and inversion, resulting in a tear of the lateral ankle structures (primarily the anterotalofibular ligament). An eversion stress to the foot or ankle will tear the medial structures (deltoid ligament), and ankle dorsiflexion with external rotation will lead to a syndesmotomic injury [6,8].

Ligamentous injuries are categorized into three gradations:

Grade I is a partial tear without laxity and only mild edema.

Grade II is a partial tear with mild laxity and moderate pain, swelling, tenderness, and instability.

Grade III is a complete rupture resulting in considerable swelling, increased pain, significant laxity, and often an unstable joint (Fig. 83.2).

Symptoms

Acutely, the injured patient will report pain, swelling, and tenderness over the injured ligaments. Some patients report a "pop" at the time of injury. Initially, they may have difficulty with weight bearing on the injured ankle and with subsequent ambulation. They may report some ecchymosis during the first 24 to 48 hours. There may be sensory symptoms in the sural, superficial peroneal, or deep peroneal nerve's distribution. Decreased function and range of motion along with instability are reported more often in grade II and grade III injuries.

Physical Examination

Inspection of the ankle will reveal edema and sometimes ecchymosis around the area of injury, depending on the extent of injury. Range of motion of the ankle joint may be limited by associated swelling and pain. Reduced

FIGURE 83.1 Ligaments of the lateral ankle.

FIGURE 83.2 Grade III ankle sprain with a complete tear of the anterior talofibular ligament.

dorsiflexion may predispose the joint to an ankle sprain [9]. Palpation should include the anterior talofibular and calcaneofibular ligaments, syndesmotic area, and medial deltoid ligament. In addition, the examiner should palpate the distal fibula, medial malleolus, base of the fifth metatarsal, cuboid, lateral process of the talus (to assess for a possible snowboarder's fracture), and epiphyseal areas to assess for any potential fractures [10,11]. The patient should be examined for strength deficits, or reflex abnormalities, which could reveal concurrent injury. Although it is uncommon, ankle inversion injuries are sometimes associated with

peroneal nerve injury and may result in sensory changes on the dorsum of the foot (superficial peroneal nerve) or the first web space (deep peroneal nerve). Deep peroneal nerve injury could result in decreased strength in dorsiflexion and eversion. If a fracture is not suspected, single-leg balance could be tested to assess the extent of proprioceptive compromise.

Ankle stability should be examined through a variety of tests and compared with the noninjured side to assess the amount of abnormal translation in the joint. The anterior drawer test of the ankle will assess the integrity of the anterior talofibular ligament. It is performed by plantar flexing the ankle to approximately 30 degrees and applying an anterior force to the calcaneus while stabilizing the tibia with the other hand. Increased translation compared with the other side implies injury to the anterior talofibular ligament. Studies in cadavers suggest that the test is accurate in detecting abnormal lateral ankle motion, with 100% sensitivity and 75% specificity [12,13]. The talar tilt test (Fig. 83.3) is performed with the ankle in a neutral position and assesses the integrity of the calcaneofibular ligament [13]. The squeeze test (Fig. 83.4) is used to diagnose a syndesmotic injury. It is performed by squeezing the proximal fibula and tibia at the midcalf and causes pain over the syndesmotic area. Similarly, the external rotation stress test is performed by placing the ankle in a neutral position and externally rotating the tibia, leading to pain in the syndesmotic region [14]. Unfortunately, several studies have demonstrated poor correlation between clinical stress test results and the degree of ligamentous disruption [15].

Functional Limitations

The patient may have difficulty in walking secondary to pain and swelling. Proprioception and balance on the injured ankle will be abnormal as noted by greater

FIGURE 83.3 The talar tilt (inversion stress) test of the ankle.

difficulty with single-leg standing on the injured leg [16]. The athlete will have difficulty with return to play until swelling and pain have diminished and rehabilitation is nearly completed. Incomplete recovery or inadequate rehabilitation may predispose the patient to reinjury [17]. Of note, the single-leg balance test can be helpful in predicting which athletes may sustain an ankle injury during the course of the upcoming season [18]. Chronic ankle sprains can result in mechanical instability, with objective instability or laxity noted on examination in all patients [19].

Diagnostic Studies

Standard anteroposterior, mortise, and lateral radiographs should be considered in cases in which there is tenderness over the lateral malleolus, ankle joint, syndesmosis, or other bony structure to rule out an underlying fracture [6,10]. The Ottawa ankle rules were developed and validated to clarify the indications for these ankle radiographs. The rules recommend imaging when there is tenderness along the lower 6 cm of the tibia or fibula, the navicular, or the fifth metatarsal head and an inability to bear weight

FIGURE 83.4 The squeeze test detects tears of the syndesmosis. The test result is positive when squeezing of the midcalf produces pain in the distal interosseous membrane and syndesmosis.

immediately after injury and in the emergency department. Adherence to these rules has shown a 30% reduction in radiography use while missing no major fractures [10,11]. At 4 to 6 weeks, a slowly healing lateral ankle injury without significant pain resolution or improvement should be evaluated radiographically, especially if an initial radiograph was not obtained.

A magnetic resonance imaging scan can help identify the soft tissue disease as well as evaluate the osteochondral joint surface when the ankle does not heal despite adequate rehabilitation. Osteochondral injuries may not be seen immediately but occur later, especially in cases with chronic instability. Stress radiographs are optional and have questionable reliability because of the great range of normal joint movement [20]. Ultrasonography may be used to further evaluate the soft tissue structures of the ankle, including ligament injury and associated tendon subluxation. Advantages of ultrasonography include the lack of radiation and relatively low cost [21].

Differential Diagnosis

High ankle sprain, syndesmotic sprain
 Osteochondral fracture of the talar dome
 Neurapraxia of the common, superficial, or deep peroneal nerve
 Fracture of the lateral process of the talus (snowboarder's fracture)
 Avulsion or fracture of the tip of the fibula
 Fracture of the base of the fifth metatarsal
 Peroneal tendon injury
 Subtalar joint instability
 Posterior impingement or fracture of the os trigonum

Treatment

Initial

Protection, relative rest, ice, compression, and elevation (PRICE) are the proposed mainstay of initial treatment and are introduced immediately [22]. However, there appears to be insufficient evidence to determine the true effectiveness of RICE for acute ankle sprains [23]. It intuitively makes sense to use crutches if weight bearing causes pain. The crutches can be discontinued as ambulatory pain declines (usually in 2 to 3 days). Grade II and grade III sprains may require longer use of assistive devices. Patients should be cautioned to avoid hanging the ankle in a plantar flexed position because it may stretch the injured anterior talofibular ligament. Positioning in maximum dorsiflexion also minimizes resultant joint effusion. Plastic removable walking cast boots or air splints are occasionally used in higher grade injuries until pain-free weight bearing is achieved. These may be used for weeks to months, depending on the extent of injury. Caution should be taken with prolonged immobilization as a systematic review of randomized controlled trials suggests that prolonged immobilization (more than 4 weeks) is less effective than early functional treatment [24]. Local ice applications for 20 to 30 minutes three or four times daily combined with compression immediately after injury is effective in decreasing edema, pain, and dysfunction. Nonsteroidal anti-inflammatory drugs may be employed to decrease pain and inflammation. Other therapeutic modalities, including diathermy, electrotherapy, and therapeutic ultrasound, have not been shown to be effective.

Rehabilitation

The rehabilitation of ankle sprains has moved toward earlier mobilization in hopes of minimizing swelling, decreasing pain, and preventing chronic ankle problems [25,26]. Active range of motion in all planes is initially performed without resistance as soon as tolerated. Dorsiflexion and eversion strengthening can be started with static exercises and progress to concentric and eccentric exercises with tubing when the patient tolerates pain-free weight bearing. Double-leg toe raises should progress to single-leg toe raises and can be done in water if they are not tolerated on land. Endurance and lower extremity muscle strengthening exercises are incorporated and increased as tolerated by the patient. Proprioception training can start in a seated position and then advance to standing balance exercises. Standing

exercises begin with single-leg stance while swinging the raised leg. Then, single-leg squats are required. Finally, exercises progress to single-leg stance and functional or sport-specific activity, such as dribbling, catching, or kicking. A more recent randomized study comparing PRICE therapy with early mobilization in patients with grade I or grade II ankle sprains reported better functional recovery in the first 2 weeks after injury in the early mobilization groups. There were no long-term differences at 16 weeks, and reinjury rate was the same for both groups [25]. A supervised program appeared to provide better results than a conventional home program [27].

Several studies have highlighted the importance of proprioceptive training in early recovery from ankle sprains and chronic functional instability. The study by Bahr and Bahr [28] of volleyball players demonstrated a 21% reduction in ankle sprains the first year and 49% reduction the second year in athletes who performed balance exercises. In addition, they reported fewer recurrent ankle sprains, and patients with more than one sprain benefited the most. A systematic review by McKeon and Hertel [29] showed that proprioceptive and balance training does in fact improve recovery acutely and can reduce recurrence rates of injury. Therefore, proprioceptive and balance exercises should be incorporated into the rehabilitation program as soon as possible.

The use of orthotic bracing is somewhat controversial. Earlier studies have suggested that bracing and taping may decrease recurrent injury rates in the previously injured ankle, but they have not been shown to be effective in athletes without a prior injury [30,31]. Beynnon and colleagues [30] studied 182 patients with first-time grade I and grade II ankle ligament sprains and showed that treatment with the air stirrup brace combined with an elastic wrap provided earlier return to preinjury function than with use of the air stirrup brace alone, an elastic wrap alone, or a walking cast for 10 days. Interestingly, a more recent meta-analysis suggests that the use of an ankle brace or ankle tape has no effect on enhancing proprioception in individuals with recurrent ankle sprains or who have functional ankle instability [32]. These studies suggest that the decrease in injury rates is due to something other than enhanced proprioception of the ankle.

Despite these findings, many athletes will consider using a brace to prevent a recurrent sprain. A study by Putnam and coworkers [33] suggested that use of ankle braces in healthy competitive recreational soccer players did not significantly affect performance in speed, agility, or kicking accuracy. The authors proposed the need for future studies to investigate the impact on athletes with ankle injuries.

Procedures

Procedures are generally not indicated for ankle sprains.

Surgery

Surgery is rare for ankle sprains. Most grade III ankle sprains with complete tears of the anterior talofibular ligament and instability are *not* treated surgically unless they result in chronic instability. If necessary, surgical repair may be completed after the sports season and is usually successful.

Reconstruction of the lateral ankle ligaments involves anatomic reconstruction of the ligament (modified Brostrom) and tendon weaving through the fibula (Watson-Jones, Chrisman-Snook) [34]. The direct repair of the ligament, even years after the injury, can be highly successful. Despite the various techniques, an extensive literature review recommended the need for randomized controlled studies to determine the relative effectiveness of surgical and conservative treatment for acute injuries of the lateral ligament complex of the ankle [35].

Potential Disease Complications

Recurrent sprains may lead to both mechanical (gross laxity) and functional (giving way) instability. The patient may present with undiagnosed secondary sources of pain, and these must be sought (see the section on differential diagnosis). Chronic intractable pain is another potential complication.

Potential Treatment Complications

Lack of recognition of and the prevalence of subacute sequelae in ankle sprains may lead to undertreatment and subsequent chronic pain or instability. Nonsteroidal anti-inflammatory drugs may cause gastric, hepatic, or renal complications. Prolonged immobilization can lead to inflexibility, muscle atrophy, and longer time loss from work or sport. Return to work, sport, or activity before adequate healing and rehabilitation may result in chronic pain and giving way (functional instability) and gross laxity (mechanical instability). As noted, heat and contrast baths should be avoided during the acute stage of injury as these modalities could promote swelling and bleeding. Finally, surgical complications could include joint injection, loss of range of motion, and compromised gait.

M20.12 Hallux valgus (acquired), left foot

Bunion

Definition

The term *bunion* stems from the Latin word *bunio*, which means “turnip,” an image suggestive of an apparent growth or enlargement around the joint. The medical term for this is *hallux valgus*. There is no similar Latin term for the fifth toe, so a similar process involving the fifth metatarsophalangeal (MTP) joint is called a bunionette. Hallux valgus is a common deformity of the forefoot and the most common deformity of the first MTP, often causing pain (Figs. 84.1 and 84.2). The pathophysiologic process stems from both the proximal phalanx and the metatarsal bone. The proximal phalanx deviates laterally on the head of the first metatarsal, exacerbated by the pull of the adductor hallucis muscle. The lateral capsule becomes contracted, and the medial structures are attenuated. The metatarsal

deviates medially, but the underlying sesamoids remain in their relationship to the second metatarsal, thus creating dissociation of the metatarsal-sesamoid complex. As these two processes occur together, the pull of the abductor hallucis moves more plantarward and the pull of the extensor tendon moves laterally, causing pronation and further lateral deviation of the great toe, respectively. As the metatarsal head becomes more uncovered, a prominent medial eminence, or bunion, is apparent. There is a bursa between the metatarsal head and the skin that may become inflamed and painful. Depending on the amount of axial rotation of the first metatarsal and pronation of the toe, the first ray becomes dysfunctional, leading to increased weight bearing on the more lateral metatarsal heads and “transfer metatarsalgia,” causing pain under the plantar aspect of the forefoot [1].

The etiology of hallux valgus is multifactorial and can be either intrinsic or extrinsic [2]. The intrinsic causes are essentially genetic and are related to hypermobility of the first ray (hallux metatarsal) at its articulation with the medial cuneiform. Ligamentous laxity (e.g., Marfan syndrome, Ehlers-Danlos syndrome) can lead to this deformity as well as to variations in the shape of the metatarsal head (i.e., a rounder head is less stable than a flat one). Another contributing factor is metatarsus primus varus, or medial deviation of the first metatarsal, which is thought to be associated with a juvenile bunion [3]. Pes planus and first metatarsal length have also been evaluated for their contribution to hallux valgus, but findings are equivocal [4].

The principal extrinsic cause is inappropriate, nonconforming footwear, with abnormal valgus forces creating deformity [5]. This is particularly notable in women who wear high-heeled shoes with narrow toe boxes. The ratio of hallux valgus between women and men has been reported to be 15:1 [6].

Symptoms

Presenting symptoms can vary. The patient may complain only of a painless prominent medial eminence. However, more commonly, there will be pain that is worse when constrictive shoes are worn and relieved by walking barefoot or with open-toed shoes. If there is significant arthritis,

FIGURE 84.1 Anatomy of a bunion.

FIGURE 84.2 Clinical photograph demonstrating a bunion or hallux valgus deformity. Note also the pronation of the digit.

patients may have pain throughout range of motion of the MTP joint while walking. The bunion may become red and inflamed as the bursa enlarges and overlying skin becomes abraded by the shoe. The patient will have difficulty finding comfortable shoes. As the hallux deviates into increased valgus, it tends to impinge on the medial aspect of the pulp of the second toe, causing pressure and soreness [7].

Physical Examination

There is generally an obvious medial enlargement overlying the metatarsal head, with occasional signs of inflammation (bursitis). The great toe will be laterally deviated, and with progression of deformity, it will be pronated (axially rotated). There may be splaying of the forefoot and callosities visible under the metatarsal heads of the lesser toes. Metatarsalgia—tenderness under the metatarsal heads—may also be seen even without a callus. Passive extension of the hallux MTP joint will reveal possible limitation of range of motion (normally approximately 70 degrees). This may indicate concomitant degenerative joint disease of the MTP joint. Mobility of the hallux at the first metatarsal-medial cuneiform joint is assessed in relation to the second ray. Hammer toes are commonly noted as a consequence of the crowding in the shoe by the great toe. Depending on the patient's medical history (e.g., diabetes), the neuromuscular evaluation is important to assess for any vibratory loss, two-point discrimination loss, or other indications of neurologic compromise. Otherwise, the neurologic examination findings should be normal.

Functional Limitations

Limitations are principally in walking long distances and wearing shoes with a narrow toe box or high heels for prolonged periods. As hallux valgus progresses, arthritis may become a component and lead to stiffness and pain with any activity (biking, hiking, walking short distances, or even standing).

Diagnostic Studies

Weight-bearing plain radiographs will provide most of the necessary information. The anteroposterior view (Fig. 84.3) demonstrates the angle (Fig. 84.4) between the first and second metatarsals (intermetatarsal angle). The congruency of the first MTP joint can also be assessed for any evidence of arthritis. These all have a bearing on any proposed surgery [8,9].

Differential Diagnosis

- Gout
- Hallux rigidus
- Rheumatoid arthritis
- Infection

Treatment

Initial

Nonsteroidal anti-inflammatory medications and analgesics may be used to alleviate pain. However, key measures include education about footwear, namely, shoes with low heels, well-cushioned soles, extra depth, and broad toe boxes. Many orthoses are available and are of varying efficacy. These include sponge wedges to be placed in the first web space, more formal braces that attempt to pull the hallux into a more neutral position, and custom-molded orthotic appliances to resist foot pronation and to support the arch.

A study showed promising results of a total-contact insole with a fixed toe separator that improved pain, walking ability, and the radiographic hallux valgus angle in patients with painful hallux valgus treated nonoperatively [10].

Rehabilitation

Once the structural deformity has progressed, physical therapy has a limited role. This includes mobilization of the first MTP joint and strengthening of the intrinsic muscles of the foot, which may improve symptoms, as well as focus on gait training [11]. Distraction techniques like varus stretching or toe spacers may also be useful.

Procedures

Local anesthetic and steroid injection into the first MTP joint may provide short-term pain relief but is certainly not curative and generally not recommended because steroid injections may have a deleterious effect on the soft tissue and cartilage.

Surgery

After conservative management has failed, surgery is a consideration. Over the years, a vast array of different surgical procedures have been described [3,12]. Furthermore, no single procedure has provided sufficient evidence of being superior to any other. The complication and recurrence rates can be relatively high, and satisfaction of the patient is difficult to achieve. A study reported that the desired outcome of surgery for patients is threefold: a painless great toe that “when wearing conventional shoes, gives no problems,” an improvement in the bursitis and appearance of the bunion, and the ability to walk as much as they wish [13]. These are not unreasonable goals, but it is very important to counsel patients preoperatively, explaining the complications and that there are no guarantees they will be able to return to wearing high-heeled fashionable footwear [14]. The principal goals of surgery are to relieve pain and to provide a foot capable of wearing a shoe.

The type of surgery, whether it is a distal soft tissue procedure [15] combined with a proximal metatarsal osteotomy, a distal osteotomy alone, or even an MTP arthrodesis, depends on the presenting anatomic deformity and its complexity.

Potential Disease Complications

Disease complications include ulceration of the medial eminence, metatarsalgia, callosities, hammer toe deformity, and stress fractures of the lesser toes.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Treatment can result in recurrent hallux valgus deformity, hallux varus from surgical overcorrection [16], and hallux extensus (cock-up toe). Procedures in which the first metatarsal is excessively shortened may result in transfer metatarsalgia. Osteonecrosis of the first metatarsal head can occur if the blood supply is disrupted significantly. Nonunion can occur with the osteotomies and MTP arthrodesis.

FIGURE 84.3 Standing anteroposterior radiograph of both feet in a patient with bilateral hallux valgus. This is more pronounced on the left. Note also the lateral deviation of the sesamoid bones.

FIGURE 84.4 The hallux valgus angle and the intermetatarsal angle are measured from the patient's standing anteroposterior radiograph.

Bunionette

Definition

A bunionette is similar to a bunion as a painful bone prominence of a metatarsal head and overlying bursa, but it involves the fifth metatarsal. The fifth metatarsal deviates laterally and the fifth toe medially. It has also been called a tailor's bunion as a cross-legged sitting position, often associated with a tailor, can cause pressure over the fifth toe and potentially encourage this deformity. Like the bunion, a bunionette has a high association with constrictive shoes and is much more common in women than in men (4:1) [4].

Symptoms

Patients may be asymptomatic or complain of irritation over the lateral eminence with tight or stiff shoe wear. Typically, when they wear open shoes without pressure over the bunionette, they have no discomfort. However, they occasionally have an inflamed bursa that is acutely painful and red. If patients adjust their shoe wear, the pain can resolve.

Physical Examination

A prominent fifth metatarsal head with a widened appearance of the forefoot is often seen. Patients may develop lateral or plantar callosities over the bone prominence. Hallux valgus may be a concomitant finding, and the foot is considered a "splay foot" if both diagnoses are present [4].

Functional Limitations

Patients typically have pain with restrictive shoe wear that is improved or absent when they are barefoot or wearing open shoes, like flip-flops, that do not put pressure over the fifth metatarsal head. Their walking tolerance may be affected when inappropriate shoes are worn.

Diagnostic Studies

Three radiographic views of the foot are obtained: anteroposterior, lateral, and oblique. Anatomic differences that can be appreciated radiographically may influence the surgical approach. These are of three types: type I, an enlarged fifth metatarsal head; type II, an abnormal lateral bowing of the fifth metatarsal shaft; and type III, a wide intermetatarsal 4-5 angle.

Treatment

Initial

Addressing the constrictive shoe wear is the first approach. Wide, extra-depth shoes or tennis shoes may help decrease the irritation and bursitis. On occasion, pronation can exacerbate the pressure of the lateral eminence against the shoe, and an orthotic can unload or change the position enough to relieve this. Patients may also take their leather shoes to a shoemaker, who can create a focal stretch over the pressure area of the shoe.

Procedures

If a callus develops, it may be débrided, or patients can be advised to use a pumice stone after daily showers to gently buff the hypertrophic tissue that accumulates laterally or plantarly. Because the discomfort from the bunionette is a pressure phenomenon, injections are not helpful. The bursitis that occasionally accompanies this deformity will improve with appropriate shoe wear and keeping the callus thin.

Surgery

More than 20 different surgical procedures have been described for the correction of a bunionette deformity. These include lateral condylectomy or distal osteotomy for type I, midshaft or distal oblique osteotomy for type II, and proximal osteotomy for type III [4].

Potential Disease Complications

Ulcerations and callosities may develop if patients continue to wear restrictive shoes.

Potential Treatment Complications

Treatment can result in recurrence of deformity, particularly with an isolated lateral condylectomy; flail toe with metatarsal head resection; malunion or nonunion of osteotomies; and vascular compromise leading to osteonecrosis, particularly with proximal osteotomies.

M25.572 Pain in left ankle and joints of left foot

M25.579 Pain in unspecified ankle and joints of unspecified foot

Definition

Chronic ankle instability is a condition characterized by a constellation of symptoms, typically including pain, weakness, and a feeling that the ankle episodically gives way, that persist after an acute lateral ankle sprain. Although chronic ankle instability may occur after a single ankle sprain, it is more commonly a sequela of repeated sprains. It has been reported to occur in up to 40% of individuals with a history of ankle sprain and as late as 6½ years after an initial injury [1]. Anatomic lateral ankle ligament laxity and mechanical instability, peroneal muscle weakness, and ankle proprioceptive deficits are three primary factors thought to cause and to perpetuate symptoms. Arthrogenic muscle inhibition

of the peroneal and soleus muscles has also been implicated as a possible contributing factor [2]. These causative factors may coexist with other pathologic processes of the ankle (such as those listed in the differential diagnosis section), which may serve to amplify and to perpetuate symptoms of functional instability. The establishment of additional diagnoses does not preclude a diagnosis of chronic ankle instability.

Symptoms

Usual symptoms are ankle pain, swelling around the lateral malleolus, weakness of the ankle evertors, and a feeling that the ankle is episodically unstable. The term *functional instability* describes the subjective sensation of “giving way” that often persists after ankle sprains [3]. Functional instability may occur in the absence of true mechanical ligament laxity and vice versa. Symptoms can continue for months or years after the original injury, range from mild to severe, and often are manifested as recurrent acute lateral ankle sprains.

Physical Examination

Objective findings are variable and can often be minimal. Potential examination findings in patients with chronic ankle instability may include reduced passive or active ankle range of motion, lateral ankle swelling, ecchymosis, lateral ankle tenderness (typically over the lateral ligament complex or peroneal tendons), weakness of the peroneal muscles, proprioceptive deficits (manifested by decreased ability to perform a single-leg stance), and mechanical laxity (demonstrated by increased motion on anterior drawer or talar tilt test compared with the contralateral ankle) [4]. Abnormal alignment, such as calcaneal varus, calcaneal valgus, or pes planus, may be evident. A limp may also be observed. Examination of the affected ankle should always be compared with the contralateral unaffected ankle.

Findings of the neurologic examination, including sensation and deep tendon reflexes, are commonly normal. Results of manual muscle testing should also be normal, with the exception of muscles surrounding the ankle that may exhibit weakness from disuse or because of pain. Balance testing commonly demonstrates deficits in the affected limb but may also reveal impairments in the contralateral ankle,

making it unclear whether these findings represent a preexisting risk for injury or are the result of previous inversion injuries [5].

Functional Limitations

Affected persons may have difficulty participating in sports, particularly high-demand sports that require quick starts and stops, cutting, and jumping (such as soccer, football, and basketball) as well as sports that involve a lot of lateral movement (such as tennis). When symptoms are severe, limitations can include difficulty with climbing steps, ambulation, and activities that require prolonged standing. It is estimated that functional instability prevents 6% of patients from returning to their occupation; 5% to 15% remain occupationally disabled 9 months to 6½ years later, whereas 36% to 85% of patients report full recovery within a period of 3 years [1,2,6,7].

Diagnostic Studies

The diagnosis is made by confirming a history of prior sprain with subsequent development of typical symptoms of functional instability in conjunction with consistent examination findings. Adjunctive diagnostic testing can be helpful in establishing the diagnosis, particularly by identifying pathologic changes and conditions that may produce similar symptoms. Testing that may be useful when the diagnosis of chronic ankle instability is being considered includes routine radiography, stress radiography, computed tomography, bone scan, magnetic resonance imaging, ankle arthrography, and magnetic resonance arthrography.
